PRINTED IN THE UNITED STATES OF AMERICA

Foreword

We take pleasure in presenting this 197th Volume of the *Transactions* of the American Institute of Mining and Metallurgical Engineers. It contains those papers selected by the Divisional Publications Committees after careful screening and condensation where necessary, from the technical papers and discussions of the Institute of Metals, Iron and Steel, and Extractive Metallurgy Divisions.

As in the past, the JOURNAL OF METALS was paged consecutively throughout 1953. There are eleven interruptions in the pagination of these Transactions because some of the material printed in the JOURNAL OF METALS is not found in this volume. This volume contains all the Metals Transactions for 1953.

There are 149 papers in the volume compared with 107 for the 1952 volume, the increase representing for the most part papers from the Institute of Metals. In this volume there are 19 papers from the Iron and Steel Division, 18 papers from the Extractive Metallurgy Division, and 112 papers from the Institute of Metals Division.

In the past few years there has been increasing use by the members of the opportunity to submit for publication Technical Notes. In this volume you will find 47 Technical Notes, or 13 more than appeared in the 1952 volume.

Discussion to various papers can be readily found by referring to the index for the papers themselves.

I wish to express thanks to the authors and the contributors of discussions. The success of our Institute will depend, in part, on the value received from good papers and discussion resulting from work on timely subjects. The total number of papers printed is limited somewhat by a budget of pages to which the members of the Divisional Publications Committees adhere by careful reading and selection. Thanks are also due to them in their difficult job.

Members of the headquarters staff are to be congratulated for the assembly of the papers into this volume, and also, for the organization of the table of contents which helps to make it possible to find the excellent material contained.

NOVEMBER 30, 1953
ASHLAND, KY.

K. C. McCUTCHEON, *Chairman*
Metals Branch Council, AIME

TECHNICAL PAPERS Institute of Metals Division

	PAGE
Density and Hydrogen Occlusion of Some Ferrous Metals. By J. H. KEELER and H. M. DAVIS.....	44
Bend Plane Phenomena in the Deformation of Zinc Monocrystals. By J. J. GILMAN and T. A. READ.....	49
Preferred Orientations in Iodide Titanium. By C. J. MCHARGUE and J. P. HAMMOND (Discussion, p. 1563)....	57
Forging of Arc-Melted Chromium. By H. L. GILBERT, H. A. JOHANSEN, and R. G. NELSON.....	63
Flow and Fracture Characteristics of the Aluminum Alloy 24S-T4 as Affected by Strain Thermal History. By S. I. LIU and E. J. RIFLING.....	66
Effect of Alloying Elements on the Behavior of Nitrogen in Alpha Iron. By L. J. DIJKSTRA and R. J. SLADEK (Discussion, p. 1560).....	69
Systems Zirconium-Molybdenum and Zirconium-Wolfram. By R. F. DOMAGALA, D. J. MCPHERSON, and M. HANSEN (Discussion, p. 747).....	73
Measurement of Internal Boundaries in Three-Dimensional Structures by Random Sectioning. By C. S. SMITH and L. GUTTMAN (Discussion, p. 1561).....	81
Effect of Tensile Strain at Low Temperatures on Deformation Twinning in Ingot Iron. By G. W. GEIL and N. L. CARWILE.....	213
Absolute Rate Theory Applied to Rate of Growth of Pearlite. By J. H. FRYE, JR., E. E. STANSBURY, and D. L. McELROY (Discussion, p. 1581).....	219
Titanium-Manganese System. By D. J. MAYKUTH, H. R. OGDEN, and R. I. JAFFEE (Discussion, p. 1566).....	225
Titanium-Tungsten and Titanium-Tantalum Systems. By D. J. MAYKUTH, H. R. OGDEN, and R. I. JAFFEE.....	231
Microstructure and Mechanical Properties of Iodide Titanium. By F. C. HOLDEN, H. R. OGDEN, and R. I. JAFFEE (Discussion, p. 1562).....	238
Titanium-Nickel Phase Diagram. By H. MARGOLIN, E. ENCE, and J. P. NIELSEN.....	243
Titanium-Carbon Phase Diagram. By I. CADOFF and J. P. NIELSEN (Discussion, p. 1564).....	248
Constitution of Titanium-Rich Ti-Cr-Al Alloys at 1800° and 1400°F. By J. L. TAYLOR and P. DUWEZ (Dis- cussion, p. 1565).....	253
Mechanism of Plastic Flow in Titanium—Determination of Slip and Twinning Elements. By F. D. ROSI, C. A. DUBE, and B. H. ALEXANDER.....	257
Observation on Scaling of Iron. By W. J. WRAZEJ (Correction, p. 572. Discussion, p. 1570).....	265
Mechanical Properties of High Purity Ti-Al Alloys. By H. R. OGDEN, D. J. MAYKUTH, W. L. FINLAY, and R. I. JAFFEE (Discussion, p. 1561).....	267
System Zirconium-Copper. By C. E. LUNDIN, D. J. MCPHERSON, and M. HANSEN.....	273
System Zirconium-Chromium. By R. F. DOMAGALA, D. J. MCPHERSON, and M. HANSEN.....	279
Kinetics of Thermal Reorientations in Cold Rolled Zirconium. By R. K. McGEARY and B. LUSTMAN (Dis- cussion, p. 1573).....	284
Vanadium-Oxygen Solid Solutions. By A. U. SEYBOLT and H. T. SUMSION.....	292
Cold-Rolling and Annealing Textures of Molybdenum Single Crystals. By N. K. CHEN and R. MADDIN (Dis- cussion, p. 1569).....	300
Grain Boundary Sliding and Migration and Intercrystalline Failure Under Creep Conditions. By H. C. CHANG and N. J. GRANT (Discussion, p. 1579).....	305
Determination of the Absolute Grain Boundary Energy of Gold at 1300°K. By F. H. BUTTNER, H. UDIN, and J. WULFF.....	313
Nature of the Creep Curve. By T. H. HAZLETT and E. R. PARKER (Discussion, p. 1577).....	318
Some Observations on Correlations Between the Creep Behavior and the Resulting Structures in Alpha Solid Solutions. By O. D. SHERBY and J. E. DORN.....	324
Creep Properties of Commercially Pure Titanium. By W. R. KIESSEL and M. J. SINNOTT.....	331
Occurrence of Chi Phase in Molybdenum-Bearing Stainless Steels. By P. K. KOH.....	339
Effect of Small Additions of Oxygen on Lattice Constants and Hardness of Zirconium. By R. M. TRECO.....	344
Development of Mechanical and Magnetic Hardness in a 10 Pct V-Co-Fe Alloy. By R. W. FOUNTAIN and J. F. LIBSCH.....	349
Thermal and Dilatometric Investigation of the Alloys of Cobalt with Chromium and Molybdenum. By A. G. METCALFE.....	357
Residual Stresses Introduced During Metal Fabrication. By K. R. VAN HORN (Institute of Metals Division Lecture, 1953).....	405
Directional Properties of 2S Aluminum. By K. T. AUST and F. R. MORRAL.....	431
Some Applications of the Thermodynamic Theory of Irreversible Processes to Physical Metallurgy. By E. S. MACHLIN.....	437
Measurement of Particle Sizes in Opaque Bodies. By R. L. FULLMAN.....	447
Stabilization of the Austenite-Martensite Reaction in a High Chromium Steel. By S. C. DAS GUPTA and	

B. S. LEMENT.....	530
Effects of Macrostructure on the Performance of Alnico Permanent Magnets. By D. G. EBELING and A. A. BURR.....	537
Vanadium-Uranium Constitutional Diagram. By H. A. SALLER and F. A. ROUGH.....	545
Silver-Cadmium Eutectoid. By G. R. SPEICH and D. J. MACK.....	549
Formation of Deformation Bands in Al-3 Pct Mg Monocrystals During Cold Rolling. By J. HERENGUEL, P. LACOMBE, and P. LELONG.....	559
Statistical Grain Structure Studies: Plane Distribution Curves of Regular Polyhedrons. By F. C. HULL and W. J. HOUK (Discussion, p. 1570).....	565
Effect of Dissolved Sulphur on the Surface Tension of Liquid Copper. By C. F. BAES, JR. and H. H. KELLOGG.....	643
Electron Microscope Study of the Effect of Cold Work on the Subgrain Structure of Copper. By L. DELISLE.....	660
Martensite Habit Plane in Quenched Ti-Mn Alloys. By Y. C. LIU and H. MARGOLIN.....	667
Recrystallization of a Cold-Rolled Copper Single Crystal. By Y. C. LIU and W. R. HIBBARD, JR. (Discussion, p. 1568).....	672
Rate of Formation of Isothermal Martensite in Fe-Ni-Mn Alloy. By R. E. CECH and J. H. HOLLOMON.....	685
Identification of the Precipitate Accompanying 885°F Embrittlement in Chromium Steels. By R. M. FISHER, E. J. DULIS, and K. G. CARROLL.....	690
Densification and Kinetics of Grain Growth during the Sintering of Chromium Carbide. By H. J. HAMJIAN and W. G. LIDMAN.....	696
Deformation of Ferrite Single Crystals. By F. L. VOGEL, JR. and R. M. BRICK.....	700
Vapor Pressure of Silver. By C. L. McCABE and C. E. BIRCHENALL.....	707
Vapor Pressure of Silver over Silver-Gold Solid Solutions. By C. L. McCABE, H. M. SCHADEL, JR., and C. E. BIRCHENALL.....	709
Metallographic Observations of the Deformation of High-Purity Magnesium in Creep at 500°F. By A. R. CHAUDHURI, N. J. GRANT, and J. T. NORTON.....	712
Revealing the Subgrain Structure of Aluminum. By M. S. HUNTER and D. L. ROBINSON.....	717
Alpha Solid-Solution Area of the Cu-Mn-Sn System. By C. W. FUNK and J. A. ROWLAND.....	723
Recrystallization and Stored Energy. By H. P. LEIGHLY, H. L. WALKER, and J. W. MARX.....	809
Magnetic Annealing of a Co-Fe Alloy. By A. H. GEISLER, J. P. MARTIN, E. BOTH, and J. H. CREDE.....	813
Order-Disorder Transformation in Cu-Au Alloys near the Composition CuAu. By J. B. NEWKIRK.....	823
Self-Diffusion of Iron in Iron Oxides and the Wagner Theory of Oxidation. By L. HIMMEL, R. F. MEHL, and C. E. BIRCHENALL.....	827
Electrical Resistance of Titanium Metal. By J. L. WYATT.....	903
Microscopical Examination of Tin Bronzes in the Alpha Range. By E. C. W. PERRYMAN.....	906
Grain Boundary Attack on Aluminum Hydrochloric Acid and Sodium Hydroxide. By E. C. W. PERRYMAN.....	911
Martensite Nucleation in Substitutional Iron Alloys. By J. C. FISHER.....	918
Calculation of Martensite Nucleus Energy Using the Reaction-Path Model. By J. C. FISHER and D. TURNBULL.....	921
Further Progress in the Development of Mg-Zr Alloys to Give Good Creep and Fatigue Properties Between 500° and 650°F. By C. J. P. BALL, A. C. JESSUP, P. A. FISHER, D. J. WHITEHEAD, and J. B. WILSON.....	924
Textures of Rolled and Annealed Iodide Zirconium. By J. H. KEELER, W. R. HIBBARD, JR., and B. F. DECKER.....	932
Anelastic Behavior of Pure Gold Wire. By D. R. MASH and L. D. HALL.....	937
Influence of Aluminum and Silicon Deoxidation on the Strain Aging of Low-Carbon Steels. By W. C. LESLIE and R. L. RICKETT.....	1021
Some Properties of Columbium Containing Nitrogen. By C. Y. ANG and C. WERT.....	1032
System Zirconium-Boron. By F. W. GLASER and B. POST.....	1117
A Study of Some Binary Hafnium Compounds. By F. W. GLASER, D. MOSKOWITZ, and B. POST.....	1119
Creep Behavior of Extruded Electrolytic Magnesium. By C. S. ROBERTS.....	1121
High Pressure Oxidation Rate of Metals—Copper in Oxygen. By W. MCKEYAN and W. M. FASSELL, JR.....	1127
Plasticity of Columbium Single Crystals. By R. MADDIN and N. K. CHEN.....	1131
Electrical Resistivity of Liquid Metals and of Dilute Liquid Metallic Solutions. By E. SCALA and W. D. ROBERTSON.....	1141
A Rationalization of Measured High Temperature Properties of Fe-Cr-Co-Ni Alloys. By J. D. NISBET and W. R. HIBBARD, JR.....	1149
Subgrain Formation in High-Purity Aluminum During Creep at High Temperatures. By A. M. GERVAIS, J. T. NORTON, and N. J. GRANT.....	1166
Inhomogeneity in Creep Deformation of Coarse Grained High Purity Aluminum. By H. C. CHANG and N. J. GRANT.....	1175
Plastic Stress-Strain Relations for Aluminum Alloy 14S-T6 Subjected to Combined Tension and Torsion. By J. MARIN and H. A. B. WISEMAN.....	1181
Deformation Mechanisms in Alpha Titanium. By E. A. ANDERSON, D. C. JILLSON, and S. R. DUNBAR.....	1191
Effects of Solid Solution Alloying on the Cold-Rolled Texture of Titanium. By C. J. MCHARGUE, S. E. ADAIR, JR., and J. P. HAMMOND.....	1199
The Ternary System Ti-Ta-C. By J. G. McMULLIN and J. T. NORTON.....	1205
System Titanium-Chromium-Iron. By R. J. VAN THYNE, H. D. KESSLER, and M. HANSEN.....	1209
Plastic Deformation of Rectangular Zinc Monocrystals. By J. J. GILMAN.....	1217
Variation of Plastic Properties with Annealing Procedure in Zinc Single Crystals. By C. H. LI, J. WASHBURN, and E. R. PARKER.....	1223
Recovery in Single Crystals of Zinc. By R. DROUARD, J. WASHBURN, and E. R. PARKER.....	1226
Plastic Deformation of Single Crystals of Copper. By J. J. BECKER and J. N. HOBSTETTER.....	1231
Orientation Relationships in the Recrystallization of Deformed Copper Single Crystals. By J. J. BECKER and J. N. HOBSTETTER.....	1235
Age Softening of Beta Brass. By H. GREEN and N. BROWN.....	1240
Plastic Deformation of Iron Between 300° and 772°K. By D. F. GIBBONS.....	1245
Rate of Propagation of Martensite. By R. F. BUNSHAH and R. F. MEHL.....	1251
Decay of Lattice Defects Frozen into an Alloy by Quenching. By A. E. ROSWELL and A. S. NOWICK.....	1259
Measurement of Approximately Cylindrical Particles in Opaque Samples. By R. L. FULLMAN.....	1267
The Cold Rolled Texture of Titanium. By D. N. WILLIAMS and D. S. EPPELSHEIMER.....	1378
Neptunium-Aluminum Intermetallic Compounds. By O. J. C. RUNNALLS.....	1460
Diffusion and Solubility of Boron in Iron and Steel. By P. E. BUSBY, M. E. WARGA, and C. WELLS.....	1463
Effects of Temperature on the Flow and Fracture Characteristics of Molybdenum. By J. H. BECHTOLD.....	1469
Bending of Molybdenum Single Crystals. By K. T. AUST, R. MADDIN, and N. K. CHEN.....	1477
Kink Band Formation in High Purity Aluminum During Creep at High Temperatures. By A. M. GERVAIS, J. T. NORTON, and N. J. GRANT.....	1487
The Properties of Sand Cast Mg-Th-Zn-Zr Alloys. By K. E. NELSON.....	1493
Titanium-Rich Regions of the Ti-C-N, Ti-C-O, and Ti-N-O Phase Diagrams. By L. STONE and H. MARGOLIN.....	1498
On the Theory of the Formation of Martensite. By M. S. WECHSLER, D. S. LIEBERMAN, and T. A. READ.....	1503

Iron and Steel Division

Evaluation of the pH and Conductivity Methods of Slag Control. By P. D. S. ST. PIERRE (Correction, p. 572. Discussion, p. 1552)	41
Accelerated Solidification in Ingots: Its Influence on Ingot Soundness. By E. MARBURG (Correction, p. 572. Discussion, p. 1553)	157
Aluminum-Oxygen Equilibrium in Liquid Iron. By N. A. GOKCEN and J. CHIPMAN	173
Thermal Conductivity Method for Analysis of Hydrogen in Steel. By B. M. SHIELDS, J. CHIPMAN, and N. J. GRANT (Discussion, p. 1551)	180
Reduction of Silicon from Blast Furnace Type Slags. By J. C. FULTON, N. J. GRANT, and J. CHIPMAN	185
Attainment of Equilibrium in Gas-Metal Reactions. By N. A. GOKCEN (Discussion, p. 1550)	191
Effect of Various Elements on Hot-Working Characteristics and Physical Properties of Fe-C Alloys. By C. T. ANDERSON, R. W. KIMBALL, and F. R. CATTOIR	525
Metallic Oxidation in Chromium Steel Melting. By D. C. HILTY, G. W. HEALY, and W. CRAFTS	649
The Influence of the Rate of Deformation on the Tensile Properties of Some Plain Carbon Sheet Steels. By J. WINLOCK (Howe Memorial Lecture, 1953)	797
Further Studies of the Tuyere Zone of the Blast Furnace. By J. B. WAGSTAFF (Correction, p. 1018)	895
Examination of a High Sulphur Free-Machining Ingot, Bloom and Billet Sections. By D. J. CARNEY and E. C. RUDOLPHY	999
Reducing Period in Stainless Steel Melting. By H. P. RASSBACH and E. R. SAUNDERS	1009
Silicon-Oxygen Equilibrium in Liquid Iron—A Revision. By J. CHIPMAN and N. A. GOKCEN	1017
Oxygen Activity in Iron Oxide Slags. By H. LARSON and J. CHIPMAN	1089
Manganese as an Indicator of Blast Furnace Slag Oxidation and Desulphurizing Power. By N. J. GRANT, J. W. DOWDING, and R. J. MURPHY	1451
Diffusion of Calcium Ion in Liquid Slag. By H. TOWERS, M. PARIS, and J. CHIPMAN	1455
Some Observations of Slag-Metal Relations in the Acid Open Hearth Steel Furnace. By G. R. FITTERER	1634
Solid Phase Identification in Partially Reduced Iron Ore. By G. BITSIANES and T. L. JOSEPH	1641
Exchange of Iron Between Liquid Metal and Iron Silicate Slags. By G. DERGE and C. E. BIRCHENALL	1648

Extractive Metallurgy Division

Forging of Arc-Melted Chromium. By H. L. GILBERT, H. A. JOHANSEN, and R. G. NELSON	63
Arc-Furnace Equipment and Its Operation at the Kennecott Utah Refinery. By H. A. SHAW and H. G. G. WHITTON	197
Tristage Crystallization Process for Utilizing Western Ferrophosphorus. By L. H. BANNING, W. E. ANABLE, and R. T. C. RASMUSSEN	423
Kinetics of the Oxidation of Galena in Sodium Hydroxide Solutions under Oxygen Pressure. By J. E. ANDERSEN, J. HALPERN, and C. S. SAMIS (Discussion, p. 1556)	554
Operations at New Cornelia Copper Smelter of Phelps Dodge Corporation. By J. W. BYRKIT	633
Effect of Dissolved Sulphur on the Surface Tension of Liquid Copper. By C. F. BAES, JR. and H. H. KELLOGG	643
Free Energy of Vaporization of Metals from 0° to 2000°C. By J. W. EVANS	655
Vapor Pressure of Zinc in the Reduction of ZnS by Cu and Fe. By A. W. BETHUNE and L. M. PIDGEON (Discussion, p. 1558)	804
Vacuum Dezincing of Desilverized Lead Bullion. By T. R. A. DAVEY	991
Thermodynamic Properties of Molybdenum Dioxide. By N. A. GOKCEN	1019
Constitution of the FeO-Fe ₂ O ₃ -SiO ₂ System at Slagmaking Temperatures. By R. SCHUHMAN, JR., R. G. POWELL, and E. J. MICHAL	1097
Solutions of Metals in Fused Salts. By D. CUBICCIOTTI	1106
Reaction of Silver with Aqueous Solutions of Cyanide and Oxygen. By G. A. DEITZ and J. HALPERN	1109
System Ag ₂ O-B ₂ O ₃ ; Its Thermodynamic Properties as a Slag Model. By G. M. WILLIS and F. L. HENNESSY	1367
Effect of Chloride on the Deposition of Copper, in the Presence of Arsenic, Antimony, and Bismuth. By V. HOSPADARUK and C. A. WINKLER	1375
Hurley Furnace and Boiler Description and Design. By E. A. SLOVER	1435
Preparation of Metallic Iron of High Purity. By G. A. MOORE (Discussion, p. 1449)	1443
Sintering Zinc Concentrates on the Blackwell 12 by 168 Ft Machine. By A. E. LEE, JR.	1631

Technical Notes

A Replica Method for Study of the Structure of Lead-Antimony Alloys. By J. BURBANK	55
Torsion Texture of 70-30 Brass and Armco Iron. By W. A. BACKOFEN and B. B. HUNDY	61
Sintering of Ultrafine Ferromagnetic Powders. By N. I. ANANTHANARAYANAN and J. F. LIBSCH	79
Retained Austenite Determinations by X-Ray Methods. By B. L. AVERBACH	87
Regarding Sigma Phase Formation. By D. S. BLOOM and N. J. GRANT	88
Low Temperature Aging in Titanium Alloys. By W. M. PARRIS, L. L. HIRSCH, and P. D. FROST	178
Lattice Parameter of Beta Titanium at Room Temperature. By B. W. LEVINGER	195
High Temperature Modification of TiCr ₂ . By B. W. LEVINGER	196
Effect of Carbon on the Volume Fractions and Lattice Parameters of Retained Austenite and Martensite. By C. S. ROBERTS	203
Slip and Grain Boundary Sliding as Affected by Grain Size. By N. J. GRANT, I. S. SERVI, and A. CHAUDHURI	217
Allotropy in the Phase ZrCr ₂ . By W. ROSTOKER	304
Preferential Etch for Use in Optical Determination of Germanium Crystal Orientation. By R. H. WYNNE and C. GOLDBERG	436
Grain Boundary Films in Boron Steels. By J. W. SPRETNAC and R. SPEISER	445
Note on Contamination of Silicon Ingots. By G. SANDOZ and H. E. STAUSS	653
Notes on the Plastic Critical Temperature in Strain-Induced Martensite Reactions. By C. D. STARR	654

Simple Devices for Approximating Constant Stress During Tensile Creep Tests. By R. L. FULLMAN, R. P. CARREKER, JR., and J. C. FISHER.....	657
Observations on the Phase TiAg. By R. J. VAN THYNE, W. ROSTOKER, and H. D. KESSLER.....	670

Evaluation of the pH and Conductivity Methods of Slag Control

by P. D. S. St. Pierre

IN recent years the use of high sulphur fuels and charges in steelmaking has necessitated rapid methods of slag control in order to insure the production of high quality steel. Several systems of control have been discussed in the literature, and of these the method described by Philbrook, Jolly, and Henry¹ has received the most attention recently. In their process the hydrogen ion concentration of an aqueous slag suspension is determined under controlled, but arbitrary conditions. The basicity of the slag may then be derived from a previously established pH-V ratio curve. Thus, by measuring the pH, some indication of the V ratio is gained, from which significant properties of the slag may be deduced. Philbrook et al. made no claims as to the theoretical justification of their treatment, but simply offered it as a rapid means of slag control. Encouraging results caused others to study the method and publish their findings.²⁻⁵ Although there was fair agreement on the efficacy of the method, no common parameter was evolved against which pH readings could be plotted. The results of the various determinations were related to such V ratios as CaO/SiO_2 and $\text{CaO}/\text{SiO}_2 + \text{P}_2\text{O}_5$ by some,¹⁻³ while others⁵ plotted against "excess lime." Rivet,⁴ however, found a simple proportionality between the hydrogen ion concentration and the sulphur content of the molten steel beneath the slag. Since slag control in North American practice is largely directed toward the efficient removal of sulphur from steel, Rivet's approach to the problem had the advantage of connecting directly a property of the slag with the impurity being removed.

In view of the diversity of parameters used it seemed probable that some fundamental point was being overlooked in seeking a relationship. Examination of the literature revealed that much emphasis had been laid on experimental detail but scant attention paid to the fundamental aspects of the hydrolysis of the aqueous slag suspension. Consequently the present investigation was undertaken with the object of rectifying this deficiency and deriving, if possible, a parameter of general application.

Petrographic studies on several matured Canadian open-hearth steel slags have shown that their major

Fig. 2—Polished section of a typical basic open hearth slag. X500. Area reduced approximately 75 pct for reproduction.

constituents are dicalcium and tricalcium silicates set in a complex matrix of iron oxides and ferrites. These phases are shown in Figs. 1 and 2. Free lime is frequently encountered in slags, but is not an equilibrium phase since on continued heating it dissolves forming silicates or ferrites. Thus, it appeared that a study of the hydrolysis of the major phases in steel slags would be profitable.

The experimental technique used in the present work was a modification of that described by the other workers.¹⁻⁵ Electrical conductivity measurements were also made on the suspensions, since Smith et al.³ had claimed advantages for this method in their paper on slag control.

Experimental Procedure

The compounds studied in this investigation were prepared in the laboratory by heating purified oxides

Table I. The pH and Conductivity Values of Aqueous Suspensions of Steel Slag Phases

Compound	Formula	pH	Conductivity, Microhm at 20°C
Wollastonite*	CaO·SiO ₂	10.7	123

* Not normally found in steel slags, but included in the series to show development of hydrolysis with increasing lime content.

(or carbonates) of the various components to suitable temperatures in platinum crucibles. Samples freshly ground to -100 mesh were used throughout the investigation, the weight taken being varied according to the purpose of the run. After weighing to ± 0.01 g accuracy, the samples were mechanically shaken for a specified time at constant temperature in 100 cc of CO₂-free distilled water. Prior to pH and conductivity determinations, slag suspensions were filtered on Whatman 42 filter papers which previously had been thoroughly washed with CO₂-free distilled water. The first 25 cc of the filtrates was used to wash the electrodes of the instruments, the remainder was used for the actual determinations.

Results

Table I shows the pH and conductivity of the leached elements resulting from shaking 0.50 g of possible open-hearth steel slag phases individually in 100 cc water for 30 min. It should be emphasized that the results relate only to determinations made under the conditions stated and therefore they do not necessarily represent equilibrium values. The pH of wüstite (FeO) was not determined, because it is very difficult to prepare pure ferrous oxide. Although several attempts were made, no really satisfactory product was obtained. There is, however, good reason to believe that its pH would be relatively low, since that of ferrous hydroxide is quoted as only 9.5 in saturated solution. If wüstite caused any pH change at all under the conditions of experiment, it would probably first form hydroxide, in which case it is reasonable to suppose the final pH would not exceed 9.5.

Table II. The pH as a Function of Weight of Steel Slag Phases in Aqueous Suspension

Compound	Formula	Weight, G	pH
Dicalcium silicate	2CaO·SiO ₂	0.05	10.8
		0.10	10.9
		0.25	11.1
		0.50	11.4

		0.025	11.9
		0.10	12.4
		0.20	12.6
		0.30	12.5
		0.50	12.6

It will be seen from Table I that the lime and calcium silicates are the most easily hydrolyzed compounds and their presence may therefore be considered as the controlling factor in determining the pH of an aqueous slag suspension. Thus, in a mixture of dicalcium and tricalcium silicates the pH will be controlled by the tricalcium silicate, provided there is sufficient quantity present to exceed the maximum pH given by dicalcium silicate. If the tricalcium silicate is present in quantities which exceed that required to produce its maximum pH, there is no means of determining the excess since the pH remains constant.

Because, from a hydrolysis point of view, lime, dicalcium and tricalcium silicates are the most important compounds in a steel slag, data on their hydrolysis as a function of weight were determined. Such data are given in Table II, and the information is shown graphically in Fig. 3. The standard experimental procedure described previously was used to obtain the data. A shaking time of 30 min was found to yield steady pH readings for all the compounds.

Fig. 3—Effect of weight on the pH of various slag phase aqueous suspensions.

For a given weight of sample the pH increases rapidly in the first few minutes, but after a shaking time of 10 min the rate of increase of pH is very low. Thus, by using 30 min periods of shaking the time factor may be ignored completely.

The curves shown in Fig. 3 immediately reveal the limitations of the pH method of slag control. It will be observed that the curves fall into two parts: at first, pH rises very rapidly with increasing weight of sample, but later the rate of increase is very small. Since slag control implies determination of the calcic mineral content of the slag, pH determinations in general will be either under or over sensitive to variations in such minerals. The choice of weight of slag sample is therefore an important factor in determining the sensitivity of the method. Some workers have used a 0.25 g sample in their investigations, while others have used 0.50 g of slag. Thus in a typical slag containing 30 to 50 pct dicalcium silicate, those using the 0.25 g sample would find the method sensitive to the weight factor and those using the 0.50 g sample would find it insensitive. Clearly in selecting the weight of sample, consideration must be given to the amount of calcic mineral likely to be encountered. If free lime is present it will be seen from the graph that little can be done, since traces of this oxide have considerable effect on the pH of the suspension. If the slag is in equilibrium free lime is generally absent, but in practice it is often found as undissolved material.

The pH of a suspension is controlled by the constituent which will cause the highest pH, and this is a function not only of the intrinsic chemical properties of the compound but also of the quantity present. This latter point may be illustrated by the data given in Fig. 3. It will be seen, for example, that 0.05 g of tricalcium silicate yields almost the same pH as 0.5 g of dicalcium silicate, and there is no way of telling from the pH determination alone which compound is predominant in its effect. If it is known at what stage of the heat the sample was taken, a fairly good guess may be made, for only the late slags are likely to contain tricalcium silicate, see Figs. 1 and 2.

Once the maximum pH of the predominating compound has been reached no determination of the quantity present can be made, for further increases have no effect on the pH. In practice this condition exists as soon as the flat part of the pH-weight curve is reached.

In the case of practical slags a complication exists in that the pH attained by the aqueous suspension will be a function of the surface of mineral exposed, since the calcic minerals may be coated by wüstite (FeO), etc., and can react only through exposed surfaces. This shielding factor may prevent the mineral from hydrolyzing to the value expected for the weight present.

This discussion provides some idea of the inherent difficulties of the pH method of slag control. It has been shown that the mode of hydrolysis of the calcic minerals prevents the hydrogen ion measurement from being an accurate method of estimating the amounts present.

Having shown that the alkalinity of slag suspensions depends on the hydrolysis of certain minerals, it will be apparent that there is no theoretical foundation for relating pH to parameters such as "V ratio" or "excess base." The partial success obtained with some of these parameters might be explained by the fact that they are, to some extent, a crude measure of the calcic minerals present in the slag. Such parameters can therefore be related to pH variations only in a general way.

The information given in Fig. 4 and Tables I and III shows that the conductivity method of control suffers from much the same disadvantages as the pH method.

The conductivity curves of the various compounds are more widely separated than the pH curves and this makes it easier to distinguish between the several phases present in a slag. Equally, however,

Fig. 4—Effect of weight on the electrical conductivity of various slag phase aqueous suspensions.

it will be seen that very minute quantities of lime present in the slag can upset measurements very considerably. Unfortunately the slopes of these curves render them unsuitable for measuring the amounts of phases present in suspensions. In this respect the conductivity method of control has no advantage over the pH technique.

Discussion

Although pH and conductivity measurements can indicate in a general way the mineralogical development of a slag as the heat proceeds, the nature of hydrolysis of the calcic minerals precludes exact quantitative measurements. In plant practice the method might, however, be used to check the type of slag being made (i.e., whether dicalcium or tricalcium silicate is present or not), provided no free lime is present, and in this application the conductivity measurement would be superior. Thus the pH or conductivity of a good steel slag could be checked and thereafter the composition of all slags adjusted to yield similar results.

Conclusions

1—It is improbable that the pH or conductivity methods of slag control can be improved by refinement of technique or more exact interpretation of results, since both methods are subject to variable sensitivity.

2—The presence of traces of undissolved lime in slag samples has a considerable effect on pH or conductivity measurements.

3—There is little theoretical justification for relating pH or conductivity results to the "V ratios" or "excess base" used by previous workers.

Density and Hydrogen Occlusion of Some Ferrous Metals

by J. H. Keeler and H. M. Davis

Densities of SAE 1020 (I) and ingot iron (II) decreased with cold rolling to minima at 60 pct reduction, whereas high-purity iron (III) was unaffected. I recovered promptly with annealing; II, sluggishly and incompletely. Hydrogen occlusion of III or II was barely affected by 60 pct cold reduction, but that of I was increased a hundredfold.

IT has been reported of iron that its density is decreased and its occlusive capacity for hydrogen is increased by cold work. One of the most interesting aspects of each of these properties is that the changes brought about by cold work are not necessarily eliminated by annealing and recrystallization. Yet recrystallization is generally accepted as restoring to their original condition the properties or characteristics altered by cold work.

A number of investigators have reported a decrease in density with cold reduction. Two^{1, 2} have shown that annealing after cold reduction may not return the density to its original value. It has been suggested¹ that cracks or flaws in inclusions produced during cold drawing contribute to the lowering of the bulk density of the metal. Extremely high-purity copper has been reported³ as not exhibiting a density decrease with cold reduction. On the other hand, calculations⁴ indicated that grain distortion by itself can produce expansion of the order of magnitude of the changes observable. Maier⁵ showed that both the density of iron and that of copper passed through a minimum with increasing cold reduction.

Although much information is available on the subject of hydrogen in steel^{6, 7} and it is well known that plastic deformation of a metal may increase its

occlusive capacity,⁸⁻¹² most of the reports pertain to charging the metal with hydrogen by cathodic deposition or with acid. Darken and Smith,¹² who employed acid charging, emphasized the great influence of cold work on the occlusive capacity of iron for hydrogen and showed the inability of a prolonged high-temperature annealing treatment to restore the occlusive capacity of cold-worked steel to the value exhibited in the hot-rolled condition.

It has been reported¹³ that an "endothermic" metal*

* Endothermic metal refers to metals like iron, nickel, copper, and platinum, which occlude hydrogen with absorption of heat, and for which the occlusion increases with rising temperature.

J. H. KEELER, Member AIME is now Research Associate, General Electric Research Laboratory, Schenectady, and H. M. DAVIS, Member AIME, is Professor of Chemical Metallurgy, The Pennsylvania State College, State College, Pa.

Discussion on this paper, TP 3434E, may be sent, 2 copies, to AIME by April 1, 1953. Manuscript, Feb. 8, 1952; revised, July 31, 1952. Los Angeles Meeting, February 1953.

This paper represents part of a thesis by J. H. Keeler submitted in partial fulfillment of the requirements for the degree of Doctor of Philosophy to The Pennsylvania State College, June 1951.

Fig. 1—Relation between density and percentage of cold reduction. The high-purity iron showed no noteworthy decrease in density.

on the other hand, has been said¹⁴ to give to iron at slightly elevated temperatures no "detectable capacity" for absorbing hydrogen. Apparently the influence of cold reduction has been found up to the recrystallization temperature.¹⁶ Tammann¹⁵ has observed considerable evolution of hydrogen from surcharged iron at the recrystallization temperature during heating.

The explanation for the influence of strain (plastic)

Table II. Possible Relation of Area to Density Loss in Annealing

	Area/Volume	Density Loss $\times 10^4$ /Volume
Hot-rolled high-purity iron annealed at 1200°C	19.6	21
Cold-reduced high-purity iron annealed at 1200°C	48.0	40

in the metal upon occlusive capacity is controversial. Whether the hydrogen in molecular form is stored in rifts or lattice imperfections as suggested by Smith¹⁷ and coworkers, and by Zapffe, Sims, and coworkers,¹⁸ or whether hydrogen atoms or protons are held by the lattice imperfections in some manner, has not been fully resolved.

Only indirect evidence has been found showing the influence of cold work or strain in iron on the occlusive capacity for hydrogen at elevated temperatures.

Experiment

Ferrous metals of three compositions were studied in this investigation: a low-metalloid rimmed ingot iron; a rimmed steel, nominally of SAE-1020 grade; and a high-purity iron. The first two were sheets of hot-rolled commercial tonnage alloys, whereas the third was obtained as a 10 lb ingot from the National Research Corp. The chemical compositions are given in Table I.

The heat treatments were done in purified helium in an airtight furnace. The densities were obtained by use of Archimedes' principle, the liquid being monobromobenzene of known density. The overall error was calculated to be possibly as large as 0.00056 g per cc, although separate density calculations for a given specimen have agreed within 0.0002 g per cc. However, the value of 0.00056 g per cc is somewhat less than the variation occasionally found between individual samples of the same material given identical treatments.

The hydrogen occlusion was determined by a technique similar to that of Sieverts. An experiment consisted of heating a metal specimen in an atmosphere of hydrogen at a constant pressure of 710 mm of mercury and measuring over mercury the equilibrium volume obtained at various temperatures. These values were then compared with the volumes obtained at the same temperatures during a blank experiment in which no hydrogen was absorbed. The difference between the volume obtained with metal present and the corresponding value found with the blank showed the amount of hydrogen absorbed by the metal at the particular test temperature.

Results and Discussion

The experiments revealed that neither the density nor the hydrogen occlusion of a ferrous material is necessarily altered appreciably by cold reduction or by subsequent annealing. Each material must be considered individually.

High-Purity Iron: The density of the hot-rolled high-purity iron was found to agree very well with the values cited by Cleaves and Thompson,¹⁹ who reported an average of 7.867 g per cc as obtained by direct determination. The value found in this investigation was 7.866 g per cc. (A density of 7.874 g per cc for exceptionally high-purity iron has been reported by Cleaves and Hiegel.²⁰)

Contrary to the widely accepted opinion that cold working decreases the density of a metal, it was found that sheets of high-purity iron cold-rolled 20, 40, 60, 80, and 90 pct from the hot-rolled condition did not undergo any noteworthy decrease in density, Fig. 1. In no case did the density of this material increase with annealing after cold reduction, Fig. 2. Actually, annealing in helium at a temperature of 1200°C decreased the density, a change which had not been foreseen.

Specimens of hot-rolled high-purity iron (about 0.10 in. thick), annealed with the above material at 1200°C, showed a small decrease in density, although not so large a loss as the thinner, cold-reduced specimens. If the density decrease at 1200°C resulted from a surface phenomenon such as volatilization or reaction with an impurity in the helium, a smaller density loss would be expected for the thicker material than for the thinner sheets. A consideration of the area-to-volume ratios and the density-loss-to-volume ratios of the hot-rolled and the cold-reduced high-purity iron specimens suggested that a surface phenomenon was involved, Table II.

Fig. 2—Relation between density and annealing temperature. The SAE 1020 exhibited a rapid increase in density during annealing at 600°C. The high-purity iron and the ingot iron showed a density decrease after annealing at 1200°C.

Fig. 3—Relation between percentage loss in density and percentage cold reduction.

Table III contains data showing the lack of influence of either cold reduction or annealing upon the density of the high-purity iron with the exception of the anneal at 1200°C.

Ingot Iron: The density of the ingot iron was found to decrease with increased cold deformation up to 60 pct reduction, as shown in Figs. 1 and 3. A slight increase in density was observed at 80 pct reduction, which is in agreement with Maier.⁵

The density determined for the hot-rolled ingot iron was nearly the same as that obtained for the hot-rolled SAE 1020, Table II. On the basis of purity, it might be argued that, because of the higher oxygen content, the volume of inclusions in the ingot iron would be the greater, giving that material the lower density. It was also suspected that the commercially hot-rolled ingot iron contained some strain, so that the metal was not of maximum density.

The recovery of density by the ingot iron with annealing after cold reduction showed a greater spread in values than was observed in the other materials. Careful rechecking indicated that the measured densities were correct for the individual specimens. Apparently the ingot iron was of a lower degree of homogeneity than were the other metals. In spite of the spread in the data, the recovery of density was clearly shown to be relatively small, inasmuch as the greatest recovery was only about 42 pct of the decrease resulting from cold reduction.

As did the high-purity iron, the hot-rolled ingot iron suffered a density decrease when annealed at 1200°C. The magnitude of this loss was 0.0039 g per cc.

Fig. 4—Relation between percentage loss in density and annealing temperature.

The density of the cold-reduced ingot iron after the 1200° anneal was only slightly increased over that found after the 900° anneal. This may have been the resultant of a density loss (also shown by the hot-rolled material) superimposed on a further recovery from the effects of cold reduction. If it is assumed that the same ratio obtains between the density losses of the hot-rolled and the cold-reduced ingot iron after the 1200° anneal as was observed for the hot-rolled and the cold-reduced high-purity iron, then a value close to the observed density of the un-annealed, hot-rolled ingot iron can be calculated, Table IV.

When the ratios in Table IV are assumed equivalent,

$$\frac{0.0021}{0.0040} = \frac{0.0039}{x}, \text{ and } x = 0.0074 \text{ g per cc.}$$

If the 0.0074 g per cc is added to the experimental density of the ingot iron as cold-reduced and annealed at 1200°C,

$$0.0074 + 7.8463 = 7.8537 \text{ g per cc}$$

the sum is close to the observed density of the hot-rolled ingot iron.

SAE 1020: Although the density of the SAE 1020 decreased as the cold reduction was increased, the rate of density decrease was not so rapid as was that for the ingot iron. The minimum density was reached after a cold reduction of 60 pct and, as with the ingot iron, a slight increase in density above the minimum was observed after a cold reduction of 80 pct, Figs. 1 and 3.

Annealing of the 60 pct cold-reduced SAE 1020 at 300°C for 2 hr provided negligible recovery of density. At a temperature of 400°C an unmistakable increase in the density was found and, after the anneal at 600°C, density recovery was substantially complete. Higher annealing temperatures, 900° and 1200°C, increased the density to a value even greater than that of the nominally hot-rolled condition, Figs. 2 and 4. It was evident from the microstructures of these specimens that little carbon, if any, remained in the metal after the anneal at either 900° or 1200°C. If a straight-line relationship is assumed between the density of cementite, 7.67 g per cc,²¹ and the density of high-purity iron, 7.87 g per cc, the influence of carbon upon density in the SAE 1020 containing 0.17 pct C is approximated at 0.005 g per cc. If 0.0050 g per cc is subtracted from the density of the hot-rolled SAE 1020 annealed 2 hr at 1200°C (7.8574 g per cc), a value of 7.8524 g per cc is obtained. The original hot-rolled and not decarburized material had a density of 7.8534 g per cc, which agrees well with the value obtained by correction for carbon.

The anneal at 1200°C apparently did not produce in the SAE 1020 the density decrease found in the commercially pure ingot iron and in the high-purity iron. The hot-rolled SAE 1020 agreed closely in density with the 60 pct cold-reduced SAE 1020 after both had been annealed at 1200°C.

It was reported previously that the high-purity iron exhibited no decrease in density with cold reduction of as much as 90 pct by rolling. This behavior is contrary to the theoretical prediction that crystal deformation alone can produce a density decrease of the experimentally familiar magnitude. With the same kind of deformation, however, the ingot iron and the SAE 1020 did exhibit a loss of density.

If a decrease in density with cold reduction can be associated with the presence of foreign elements in the metal, a plausible explanation of that relationship is that imperfect or uneven flow of metal occurs at phase boundaries during plastic deformation. Voids in the metal adjacent to inclusions could possibly serve in explanation of the observations.

The presence of voids in cold-worked iron or steel has been indicated by the blistering of such materials by hydrogen after acid pickling. It is also widely observed that such blisters often occur in the vicinity of inclusions in the metal. It is possible that the inability of the metal, during plastic deformation, to flow perfectly about small inclusions would both cause the voids necessary to initiate blistering and contribute to a decrease in the density of the metal.

The wide difference in density recovery with annealing of the SAE 1020 and the ingot iron suggests that different mechanisms are involved in the density decrease induced in these two metals by cold work. It would be instructive to determine the influence of various phases upon the plastic behavior of the surrounding ferrite lattice.

Hydrogen Occlusion: The first experimental values obtained for the occlusion of hydrogen by high-purity iron and by ingot iron in the hot-rolled, the 60 pct cold-reduced, and the annealed condition did not differ significantly from each other. Because this lack of influence of cold work was not anticipated by information found in the literature, several occlusion tests with annealed nickel sheet were conducted to show whether the system was sufficiently sensitive to pick up notable differences in hydrogen occlusion. Inasmuch as the values obtained for the hydrogen occlusion by nickel agreed very well with the data of Armbruster,²² confidence in the measurement was established.

The continued study of the occlusion of hydrogen revealed no large variations in the occlusive capacity of the high-purity iron or of the ingot iron, whether the metal was in the hot-rolled, the 60 pct cold-reduced, or the annealed condition, Figs. 5 and 6. The occlusive capacity of the SAE 1020 in the hot-rolled and in the annealed condition was similar to that of the high-purity iron and that of the ingot iron, Fig. 7. But the 60 pct cold-reduced SAE 1020 exhibited a phenomenal occlusive capacity for hydrogen at the lower test temperatures. At 250°C this material occluded 9.03 cc of hydrogen per 100 g of

Fig. 5—Hydrogen occlusion vs temperature for high-purity iron in various conditions.

Fig. 6—Hydrogen occlusion vs temperature for ingot iron in various conditions.

Fig. 7—Hydrogen occlusion vs temperature for SAE 1020 in various conditions. The curve for the cold-reduced material is incompletely shown here. See Fig. 8.

metal, about 24 hr being necessary for the attainment of equilibrium. This volume was approximately one hundred times the amount taken up by the hot-rolled SAE 1020, or by either of the other two irons. At 300°C, the occlusion of hydrogen by the cold-reduced SAE 1020 fell to 3.84 cc per 100 g. Here, less than 30 min was necessary for the establishment of equilibrium. A minimum occlusion was reached at 450°C, where 1.50 cc per 100 g was taken up, and the normal solubility rise with a further increase of temperature was observed at 550°C. As the metal was cooled, the curve of occlusion vs temperature did not follow the same path that it took during heating. Apparently some recrystallization (among other possible changes) had occurred at the higher test temperatures, diminishing the occlusive capacity. During cooling, a broad minimum in the hydrogen occlusion occurred at 350° to 400°C, and the amount of occlusion increased slightly at 300° and 250°C. The hydrogen occlusion of the cold-reduced SAE 1020 plotted against temperature is shown in Fig. 8, which also includes, for comparison, selected values from the literature and from this investigation for the occlusive capacity of nickel and of iron.

The density decrease and the large increase in hydrogen occlusion which were exhibited by the

Fig. 8—Hydrogen occlusion vs temperature for nickel (dotted lines 22, 23, and 24) and for iron (dashed lines 22, 25, and 26). The numbers refer to references which are the original sources of the data indicated by broken lines. The solid lines are data from this investigation. The data for iron from this research indicate the wide spread of values. The curve for the cold-reduced SAE 1020 is in remarkable contrast to the other curves.

SAE 1020 after cold reduction were not compatible with the concept of the storage of molecular hydrogen. Approximately 2.9 cc of gas was charged into 4.1 cc of this steel at 250°C, the source of the hydrogen being the gas at a pressure slightly less than 1 atm. Since the observed density decrease of 0.18 pct in this material could provide a calculated storage volume of only 0.00524 cc, storage as hydrogen gas would require a pressure of 516 atm in the voids, or 552 times the charging pressure. Yet the dissociation which makes charging possible at the test temperature, 250°C, would hardly permit the development of void pressures any greater than 1 atm.

The hydrogen-occlusion results for the three ferrous materials in various conditions and for annealed nickel were obtained by subtraction of the observed volumes from the average of the appropriate blank values. Because the blank could vary by as much as ± 1.75 pct, the very small occlusive capacity of iron for hydrogen, particularly at 250°C, occasionally produced a fallacious negative value for occlusion. Obviously, in these instances the slight occlusion of hydrogen was less than the experimental error.

Summary and Conclusions

The high-purity iron showed neither a density decrease nor any noteworthy change in hydrogen occlusion with cold reduction or annealing. Apparently the presence of impurities is necessary for a density decrease with cold reduction.

Cold reduction decreased the density of ingot iron but did not change the hydrogen occlusion of the metal. Annealing after cold reduction restored only 42 pct of the original density loss and did not influence the hydrogen occlusion.

Cold reduction decreased the density of SAE 1020

and increased the hydrogen occlusion at 250°C about 100-fold. This remarkable hydrogen occlusion decreased at higher temperatures, but remained greater than that of the unstrained material. Annealing after cold reduction eliminated the density loss and diminished the large occlusive capacity caused by cold work. The hydrogen-occlusion behavior of the SAE 1020 is not compatible with the theory of occlusion by storage of molecular hydrogen.

To reconcile the various observations, it is proposed that two varieties of voids result from imperfect plastic flow of the ferrite about inclusions or other phases during cold rolling. Hydrogen may be stored in gaseous form in the larger of such voids, which do not disappear with annealing; but it is apparently associated in some other manner with narrower imperfections which are eliminated with annealing or recrystallization.

Acknowledgment

The authors are grateful for materials and analyses provided by the Research and Development Laboratory of the United States Steel Co. Stimulating discussions with personnel of the Research Laboratory of the United States Steel Corp. and of the Research and Development section of the United States Steel Co. lent impetus to this study.

Bend Plane Phenomena in the Deformation of Zinc Monocrystals

by John J. Gilman and T. A. Read

FOLLOWING the deformation of zinc monocrystals, sharply bent basal planes are observed near several types of inhomogeneities. Three of these inhomogeneities have characteristics which are quite regular so that they can be studied and analyzed. These are compressive kink bands, "deformation bands," and the inhomogeneities near end restraints. The present paper describes experiments in which "deformation bands" were artificially produced, and bend plane phenomena are discussed in terms of dislocation theory. Also, two new bend plane phenomena are described.

The importance of bend plane phenomena in the deformation of crystals is not widely recognized. Many phenomena may be explained in a manner similar to the discussion in this paper. Jillson¹ has pointed out that the "punching effect" in zinc is a bend plane phenomenon and is not caused by prismatic slip.² Bowles³ has suggested that they may be involved in diffusionless phase changes. Cahn⁴ has discussed the role of bend plane formation in the polygonization of zinc.

Experimental Work

Tensile Kink Bands: Because of the geometrical similarity between "deformation bands" and "kink bands" (compare Fig. 1 of this paper with Fig. 1 of the paper by Hess and Barrett⁵), the band shown in Fig. 1 of this paper will be called a "tensile kink band," and that shown by Hess and Barrett will be called a "compressive kink band." It is felt that the term "deformation band" should be reserved for banded structures in polycrystalline materials such as iron.⁶

Tensile kink bands seem to form spontaneously in aluminum crystals deformed by tensile loading.⁷⁻¹⁰ In zinc and cadmium crystals they do not form in good, carefully loaded specimens.^{1,9} However, tensile kink bands can be produced artificially in zinc crystals. The present authors did this by scratching one of the flat surfaces of triangular crystals transversely with a sharp needle. Natural tensile kink bands caused by inhomogeneities sometimes appeared in deformed crystals which were identical in appearance with the artificially produced ones.

Zinc monocrystals were grown by the Bridgman method in graphite molds. Chemically pure zinc (99.999+ pct Zn) was used and the molds were sealed inside evacuated pyrex tubes during growth. The crystal cross sections were equilateral triangles with a typical base of 0.210 in. The artificial kink band shown in Fig. 1 is typical of tensile kink bands

Fig. 1—Tensile kink band in a triangular zinc crystal. X4. Area reduced approximately 25 pct for reproduction.

in zinc. The band lies between two bend planes which run from upper right to lower left and is inclined oppositely to the slip bands which are sharply bent at the two bend planes.

The general form of the artificial tensile kink bands was independent of the scratch depth (1 to 5 mils deep) and also independent of which side was scratched. These variables did cause variations, however. Deep scratches produced more localized kink bands than light scratches. Also, if the angle between the slip plane traces and a transverse scratch varied appreciably among the three sides, then localization of the resulting kink bands also varied. Furthermore, if the slip direction lay nearly parallel to the scratched side, the band was more developed near the scratched side than at the opposite edge. Scratches produced tensile kink bands for crystal orientations from $\chi_0 = 15^\circ$ to $\chi_0 = 75^\circ$.

Fig. 2 shows a scratched crystal after deformation. One triangular side lies in the plane of the photograph. The right hand tensile kink band was produced by a transverse scratch on the upper right side. The next two kink bands were the result of scratches on the front surface. The kink band at the left was caused by a scratch on the lower back side. All four bands have the same general form.

A longitudinal scratch was also made on the crystal shown in Fig. 2 to determine the effect of a scratch on the critical shear stress. The critical shear stress of the scratched region was 33.9 g per sq mm compared to 24.4 g per sq mm for the unscratched region above it.

Fig. 3 shows Laue patterns of the crystal shown in Fig. 2. Fig. 3a shows the pattern of the undeformed crystal. The orientation was $\chi_0 = 21^\circ$, $\lambda_0 = 31^\circ$. After deformation, Fig. 3b was made of the homogeneously deformed portion of the crystal. The spots are compact but split into two halves. This region was elongated 45 pct and its orientation was $\chi = 14^\circ$, $\lambda = 20^\circ$; the sine law predicts $\chi = 14^\circ$, $\lambda = 20.5^\circ$. Fig. 3c was taken near the center of the middle tensile kink band of Fig. 2. The pattern shows a range of orientations and polygonization in this region. The spread in orientation was due to the fact that the basal planes were curved (see Fig. 1) rather than flat as in the ideal case. Some may also have been the result of elastic distortions and "local curvatures." The orientation range was $\chi = 23^\circ$ to 32° , $\lambda = 30^\circ$ to 42° . It is apparent from Fig. 3 that the material inside and outside the kink band rotated in opposite directions with respect to the tension axis during deformation. The orientation calculated from the ideal configuration of Fig. 9,

Fig. 2—Tensile kink bands produced in a triangular zinc crystal by scratches prior to elongation. $\times 1/2$. Area reduced approximately 20 pct for reproduction.

$\lambda_{\text{band}} = 2\lambda_0 - \lambda = 42^\circ$, lies at the upper end of the observed range. Thus there is good agreement between the visual and X-ray observations.

To determine whether the effect of a scratch is localized or whether it extends far into a crystal, the following experiment was performed. A crystal was chemically polished and scratched transversely. Then about 0.25 mm of material was removed from each side of the specimen by means of chemical polishing. Another scratch was made on the same side of the crystal at a different place, and it was elongated in tension. An intense tensile kink band formed at the second scratch but only a faint one formed at the first scratch. The same result was obtained with a different crystal. Thus the effect of a scratch is localized initially and spreads across the diameter of a crystal as deformation proceeds.

Artificially produced tensile kink bands do not appear directly at the cross section which is scratched. They appear in the region of the undeformed crystal which is cut by a plane containing the line of the scratch and the normal to the basal planes of the crystal. This plane is one of the bend planes which bound the tensile kink band. Slip is initially inhibited only near the scratch, but after bend planes form the disturbance propagates across the width because of the self-stabilization of the kink band.

The authors have observed natural tensile kink bands near heterogeneities such as included crystals and nonmetallic inclusions. They also occur in mishandled crystals. Artificial tensile kink bands can be induced in zinc and tin crystals by scratches, but scratches have no effect for lead crystals. Schmid¹¹ showed that tensile kink bands can be induced in magnesium crystals by drilled holes. Both natural and artificial kink bands occur in variously shaped zinc crystals. In short, tensile kink bands tend to form whenever one part of a crystal lags in the reorientation process during a tensile test. Once formed, they are surprisingly stable against the large forces which tend to straighten them out. They are not observed when one portion of a crystal is softer than the rest. Two inhomogeneous regions analogous to those at end restraints are found at each end of the soft section instead. Kink bands do not form unless the hard part of the crystal is short

compared to the diameter of the crystal. Thus no kink band formed at the longitudinally scratched region in Fig. 2, although it was harder than the rest of the crystal. If the hard section is long, the large reverse bending moments at the ends do not allow bend planes to form. Finally, tensile kink bands do not form when more than one slip system is active.⁷

New Bend Plane Phenomena: Two new bend plane phenomena have been observed. The first was observed when some crystals cleaved part way through their cross sections during elongation. Tongue-like pieces of the crystals separated from the rest and bent sharply backward upon further deformation, see Fig. 4. Some bending of such a tongue-like fragment would be expected even if the specimen were not a single crystal. The bending here is very lo-

Fig. 4—Bending of a piece of a partially cleaved crystal caused by deformation of the crystal subsequent to the partial cleavage. $\times 2$. Area reduced approximately 25 pct for reproduction.

calized, however. Also, the amount of bending was large compared to the additional deformation given the crystal after the partial cleavage formed. The very sharp angle between the outer edge of the bent piece and the edge of the crystal indicates a bend plane containing the sharp angle and bisecting the angle between the slip direction of the tongue and the slip direction of the rest of the crystal. If the specimen was deformed further, it is expected that the tongue would rotate oppositely to the slip planes in the rest of the crystal in order to maintain the symmetry across the bend plane.

The other new bend plane phenomenon was caused by a longitudinal scratch on one side of a triangular crystal (orientation was $\chi_0 = 74^\circ$, $\lambda_0 = 74^\circ$). Fig. 5a shows the side of the crystal opposite the scratch after deformation, about 50 pct elongation. Fig. 5b shows the cross section. Most of the cross section behaved normally during deformation. This is on the bottom in Fig. 5a. One corner, however, behaved abnormally; its slip planes rotated oppositely to the rest of the crystal. This is on the top in Fig. 5a. Thus, a sort of longitudinal kink band formed in contrast to the transverse kink band of Fig. 1. The anomalous corner did not coincide in location with the longitudinal scratch. If the two locations were connected by lines, these lines would lie near the basal plane normals. From this, and the fact that the specimen axis nearly bisects the angle between the slip directions of the two parts of the crystal, it is concluded that this phenomenon is similar to the effects of transverse scratches. It is believed that slip inhibition near the longitudinal scratch caused

Fig. 3—Tracings of back-reflection Laue patterns. Tungsten radiation. a (left)—As-grown crystal. b (center)—After deformation, 45 pct elongation, homogeneously deformed portion. c (right)—After deformation, near center of deformation band.

Fig. 5a (left)—Side of triangular crystal opposite longitudinal scratch (scratch on back upper side) after 55 pct deformation. X2. b (right)—Cross section of same crystal. Arrow points to scratched side. Area reduced approximately 25 pct for reproduction.

local bending when the crystal was elongated. This caused a longitudinal bend plane making a right angle with the slip direction. After the bend plane was established, the slip planes of the corner on the right in Fig. 5 rotated oppositely to the rest of the slip planes, leading to the configuration of Fig. 5.

Discussion and Theory

Tensile kink bands, compressive kink bands, and the bend planes at end restraints are closely related phenomena. The geometry of these will be discussed after a general dislocation theory of bend plane formation is presented.

Dislocation Theory of Bend Plane Formation: The role of dislocations in the formation of compressive kink bands was discussed by Hess and Barrett.⁵ Their ideas can be extended by use of the dislocation theory of grain boundaries developed by Burgers¹² and by Read and Shockley.¹³ First, it should be pointed out that it is not necessary to invoke dislocation concepts in order to explain bend plane formation phenomenologically. In zinc at room temperature, slip occurs only on the basal planes and therefore is lamellar. Because of this, fact, a discontinuity in shear strain which results from slip must lie in a plane which bisects the disorientation angle between the lattices on either side of the discontinuity. If the shear discontinuity does not lie in the bisecting plane, as shown in Fig. 6a, the thicknesses of the sheared lamellae are reduced; an impossible circumstance. Fig. 6b shows that when a bend plane forms, the strain in the sheared material is given by $2 \tan \theta/2$, where θ is the disorientation angle.

In terms of dislocation theory, bend planes consist of walls of dislocations having the same sign; that is, they are grain boundaries. Defined in physical terms, they are also grain boundaries but are usually discussed as distinct phenomena because they have a different origin than ordinary grain boundaries. Bend planes are rather ideal grain boundaries in that they have only one degree of freedom; the angle between the slip directions on either side of the bend plane.

Bend planes in bent crystals decrease the energy of the system. A plastically bent zinc crystal contains an excess of positive dislocations if it is bent concavely downward. The density of excess positive dislocations is inversely proportional to the radius of curvature.⁴ These excess positive dislocations may be considered to constitute a multitude of small angle grain boundaries. The energy of this configuration may be compared with that of a bent crystal containing a single large-angle grain boundary.

The Read and Shockley expression for the energy of a grain boundary is

$$E = E_0 \theta (A - \ln \theta)$$

where A and E_0 are constants and θ is the disorientation angle. The boundary bisects θ . If ϕ is the angle between the two ends of a bent specimen and it con-

tains $M + 1$ grains, hence M grain boundaries, the orientation difference across each boundary is ϕ/M . Thus the total grain boundary energy of a specimen with variable M will be

$$E = E_0 \phi [A - \ln(\phi/M)]$$

Since ϕ/M must always be small if the theory is to be valid, this expression increases continuously with increasing M . Thus the energy is lowest if the orientation difference between the ends is contained in one boundary. However, if ϕ/M is large, and hence the theory only approximate, there may exist values of ϕ for which the energy will be lower if two twin boundaries are present instead of one large-angle boundary. The bend plane always bisects the angle between the lattices on either side of it. Also, the bend plane contains the normal to the plane containing the slip directions. This position is stable because it yields a maximum of symmetry across the bend plane and a minimum dislocation density in the bend plane. This can be verified by the method of Frank.¹⁴

Although a bent specimen having one large-angle grain boundary has a lower energy than one with many slightly disoriented grains, bend planes do not always form spontaneously in bent zinc crystals. For example, Cahn⁴ found that uniformly bent zinc crystals do not polygonize unless they are heated for several hours near the melting point. The temperature necessary to cause polygonization is lower the smaller the bend radius, and the longer the annealing time. Similar results were found for silicon ferrite by Dunn and Daniels.¹⁵ On the other hand, bend

Fig. 6—Showing that the lamellar nature of deformation by slip requires that a shear discontinuity lie in a plane which bisects the disorientation angle between the lattices on either side of the discontinuity.

Fig. 7a—Shear stresses caused by an infinite vertical wall of positive edge dislocations. From Burgers' Eq. 13. Regions of positive and negative shear stress over the xy plane.

planes form at room temperature at kink bands and the Laue pattern of Fig. 3c shows evidence of partial polygonization within a tensile kink band.

In a uniformly bent zinc crystal it is presumed that the excess positive dislocations are rather uniformly distributed in a rectangular array. Because of the mutual repulsive forces between them, they tend to remain so distributed. At high temperatures, because of thermally actuated fluctuations, they gradually join into vertical arrays and thus polygonize the bent crystal. If the initial bending is non-uniform, as it is for bend plane formation, the excess positive dislocation density on a given plane is greatest at the point of greatest bending. This configuration is stable and can attract other dislocations to itself. Consideration of an expression which Burgers¹² derived will clarify this statement.

Burgers' expression for the shear stress due to an infinite vertical wall of uniformly spaced positive edge-dislocations is

$$\sigma_{xy} = \left[\frac{G l}{2\pi(1-\nu)} \right] \frac{\pi^2 x}{a^2} \left\{ \frac{\cos h \left(\frac{2\pi x}{a} \right) \cos \left(\frac{2\pi y}{a} \right) - 1}{2 \left[\sin^2 h^2 \left(\frac{\pi x}{a} \right) + \sin^2 \left(\frac{\pi y}{a} \right) \right]^2} \right\}$$

where x, y are Cartesian coordinates; a , the spacing of the dislocations in the wall; G , the shear modulus; l , the magnitude of the slip vector of the dislocations; and ν is Poisson's ratio. The boundaries of regions of positive and negative shear stress in the xy plane are found by setting the numerator of the equation equal to zero, that is, by plotting

$$\cos h \left(\frac{2\pi x}{a} \right) \cos \left(\frac{2\pi y}{a} \right) = 1$$

This has been done in Fig. 7a. At large x the shear stress varies sinusoidally with y . It is positive in the shaded regions from $-a/4$ to $+a/4$, from $3a/4$ to

Fig. 7b—Shear stresses caused by an infinite vertical wall of positive edge dislocations. From Burgers' Eq. 13. Variation of shear stresses with x at various values of y .

$5a/4$, etc. Therefore a positive dislocation at large x within those regions would be repulsed from the wall. On the other hand the shear stress is negative in the regions $a/4$ to $3a/4$, $5a/4$ to $7a/4$, etc., and dislocations within those bands would be attracted to the wall. At small x the bands of positive shear stress become very narrow. Therefore a dislocation at small x and almost any y would be attracted to the wall.

The variation of the shear stress, σ_{xy} , with x for various values of y , is plotted in Fig. 7b. For $y = 0$ the shear stress is positive for all x and approaches infinity as $x \rightarrow 0$. For $y = a/8$ the shear is negative for small x but positive for large x .

Since the positive dislocations are inhibited from entering the wall if they lie in planes near those in which the wall already has dislocations, the wall spacing tends to be uniform. Also, a wall of positive edge dislocations is self-stabilizing. As dislocations are added to the wall, a decreases so shear stresses due to the wall become increasingly localized.

All of the bend plane phenomena which have been discussed in this paper began with nonuniform bending of specimens. It is believed that this caused a few excess dislocations of the same sign to assemble in the planes of maximum bending. Thus vertical walls were formed which became increasingly stable as more dislocations attached themselves. The actual experimental configurations are non-ideal, of course. Instead of single dislocations perhaps bend planes may be thought of as assemblies of dislocation bunches. These would behave approximately as single dislocations having large slip vectors.

Bend Planes at End Restraints: Bend planes at end restraints were first described by Mark, Polanyi, and Schmid.¹⁶ Later, Miller¹⁷ studied them systematically. Fig. 8a is taken from Miller's paper. It shows that, at the restrained end of a crystal, the

Fig. 8—Bend planes at end restraints. a (left)—Inhomogeneous deformation in a zinc monocrystal near end restrained by polycrystalline portion of rod. (After Miller.) X3. b (center)—Schematic geometry of Fig. 8a. c (right)—Homogeneous shear strain regions in Fig. 8a.

basal planes are bent during deformation. The bending is about an axis lying in the slip plane and normal to the slip direction. The bending moment reaches a maximum at the plane TF , Fig. 8b, but the maximum amount of plastic bending occurs at a plane which is normal to the slip direction and passes through point T because the material within TPF is restrained from slipping by the end restraint. Excess dislocations of the sign shown assemble along TH and form a dislocation wall. Once it is formed, the wall is stable against dispersion and maintains a position such that it bisects the angle MPF between the slip directions of the lattice on either side of it. In order to do this, TH is required to pivot about T , because the planes within TPF cannot easily change in orientation. This pivoting is a rather ideal case of stress-induced, grain-boundary migration.

Actual crystals approach the ideal behavior depicted in Fig. 1b more closely at elevated temperatures than at room temperature.² This happens because recovery (annihilation of dislocations) is rapid at elevated temperatures so that not many excess dislocations pile up adjacent to the bend plane and cause distortion. Miller showed, experimentally, that the bend plane TH always made an angle with TF of $\frac{1}{2}(\lambda_0 + \lambda)$, where λ_0 is the initial angle between slip direction and tension axis. Thus, the position of TH can be calculated for any tensile elongation from the laws of crystallographic slip.¹⁸ Also, it can be seen that the bend plane TH always bisects the angle between the initial and final slip directions, as seen from the geometry of Fig. 6b. The analysis which Miller carried out was incomplete because he did not calculate the maximum distance at which the end restraint affects the crystal, MS . Also, he did not calculate the shear strains in the various regions of the specimen.

The distance MS can be calculated. This derivation was suggested by W. T. Read in a private communication. The suggestion of McKeehan in his dis-

cussion of Miller's paper cannot be used to calculate MS because the axes of the deformed and undeformed sections do not coincide. The calculation is

$$MP = NF - PF \\ = d \csc \lambda_0 - PQ \sec \lambda,$$

and

$$MS = MP \cos \lambda + PQ$$

Miller showed that

$$PQ = d \left[\tan \lambda_0 + \cot \left(\frac{\lambda + \lambda_0}{2} \right) \right]$$

Therefore,

$$\frac{MS}{d} = \frac{\cos \lambda}{\sin \lambda_0} + \frac{1 - \cos \lambda \sec \lambda_0}{\tan \lambda_0 + \cot \left(\frac{\lambda + \lambda_0}{2} \right)}$$

With manipulation this reduces to

$$\frac{MS}{d} = \frac{\cos \lambda}{\sin \lambda_0} - \sin (\lambda_0 - \lambda) \left[\frac{1 - \cos (\lambda_0 + \lambda)}{1 + \cos (\lambda_0 - \lambda)} \right]$$

MS was calculated for Miller's data by means of the last expression and the calculated values agreed satisfactorily with the observed values.

The four regions of homogeneous shear near an end restraint are shown in Fig. 8c. In the region TPF the shear strain S_1 is equal to zero. Consideration of Fig. 6b shows that in the region TMP the shear strain is

$$S_4 = 2 \tan \left(\frac{\lambda_0 - \lambda}{2} \right)$$

The standard expression for the shear strain in the region $LMPHK$ ¹⁸ is

$$S_2 = \cot \lambda - \cot \lambda_0.$$

Since the shear strain discontinuity across TH is constant, then

$$S_2 - S_3 = S_4 - S_1$$

Hence

$$S_3 = S_2 - S_4$$

Fig. 9—Schematic drawings of an ideal tensile kink band. a (left) —Schematic geometry. b (right) —Regions of differing but homogeneous shear strain.

Thus the configuration near an ideal end restraint may be completely analyzed.

Tensile Kink Bands: Tensile kink bands in zinc crystals were also first studied systematically by Miller.¹⁰ His interpretation of them was incorrect, however, because he thought they were caused by a new form of twinning. Later authors, notably Andrade²⁰ and Jillson,¹ corrected this mistaken impression, but did not discuss the bands in detail.

If a localized portion of a crystal is harder than the rest, bending moments are created at the edges of the hard portion when the adjacent soft portions slip. The resulting excess dislocation concentrations result in dislocation walls which form along planes BP and $B'P'$, Fig. 9a, cutting the slip planes at right angles to the slip direction. These walls stabilize and tend to maintain equal angles between themselves and the slip directions on either side. As slip causes the basal planes outside the band to rotate counterclockwise, the dislocation walls at BP and $B'P'$ cause the basal planes within the band to rotate equally clockwise. When the bend planes become saturated with dislocations, dislocations of the same sign begin to pile up outside. These cause curvature of the basal planes near the bend planes to give the non-ideal configuration of Fig. 1.

The drawing of Fig. 9a shows the schematic geometry of an ideal tensile kink band. The angle between the slip planes within the kink band and the tension axis is $(2\lambda_0 - \lambda)$ where λ_0 and λ are the initial and final angles between the slip direction and the tension axis respectively.

It should be noted that the rotation of the slip planes within $BPP'B'$ may occur either by means of reverse slip in $BPP'B'$ or by a bulk rotation of the region combined with lateral movement of the bend planes (rotation of the bend planes may occur but it causes no rotation in the region $BPP'B'$). Since no experimental evidence of reverse slip was found, it is believed that the latter mechanism operates when an ideal tensile kink band forms. The rota-

tion of the planes relative to the sides BB' and PP' is the result of normal forward slip in $B'BR$ and $PP'R'$. This latter rotation causes the slip planes within a kink band to take the angle α with the side BB' and the side BB' takes an angle γ with the tension axis. If the angle α is known, γ may be calculated as follows:

$$\gamma = \beta - (\alpha - \lambda_0) \\ = 3\lambda_0 - (\alpha + 2\lambda)$$

Fig. 9b shows the various regions of homogeneous shear strain. The shear strains are

$$S_1 = 0 \\ S_2 = S_2' = 2 \tan \beta / 2 \\ S_3 = S_3' = \cot \alpha - \cot \lambda_0 \\ S_4 = S_4' = \cot \lambda - \cot \lambda_0$$

Since the shear strain discontinuities across BP and $B'P'$ are constant, then

$$S_2 = S_4 - S_3 = S_2' = S_4' - S_3'$$

Thus an ideal tensile kink band is completely determined except for thickness if the angle α , as well as λ_0 and λ , is known.

Actual tensile kink bands deviate from the ideal case because some slip occurs in the region $BPP'B'$ after the band has formed. This was shown by forming a kink band in a specimen, then electropolishing to remove the slip lines, and finally elongating the specimen an additional 10 pct. Slip lines could be seen within the kink band, at the bend planes, and outside the kink band where the deformation was homogeneous. This means that the planes BP and $B'P'$ do not represent static discontinuities since some material passes through them.

Compressive Kink Bands: Compressive kink bands were discovered by Orowan²¹ in cadmium monocrystals which had very low orientation angles. He believed that an entirely new mechanism of deformation was involved, but Hess and Barrett⁵ were able to form compressive kink bands slowly in zinc and thought that the mechanisms of slip and bend plane formation explained their observations. Compressive kink bands differ in their mode of formation from tensile kink bands. Hess and Barrett⁵ showed that buckling is necessary for compressive kink-band formation. This buckling must be that of a beam with restrained ends. If the ends are not restrained, the crystal simply bends uniformly. This is consistent with the theory discussed above. It is expected that a crystal bent with free ends would polygonize if annealed, but bend planes would not form in it during deformation. If the ends of the crystal are restrained, the crystal buckles with two points of inflection in the displacement curve at which the shear stresses are a maximum. Shear yielding occurs here first, according to Hess and Barrett. Thus, positive and negative dislocations flow out of this region along the length of the crystal (the basal planes in this case must be almost parallel to the compression axis) toward the points of maximum bending and minimum shear stress. They stop somewhere in between and assemble into dislocation walls. These oppositely directed walls or bend planes constitute the initial stage in the formation of a compressive kink band.

An important distinction between compressive and tensile kink bands is that the former can be formed in an otherwise homogeneous zinc crystal while the latter form only in crystals containing heterogeneities. Compressive kink bands form in a

particular type of test (compression of thin rod with restrained ends) in crystals having rather restricted orientations. Tensile kink bands form in a particular test (axial tension of thin rod) in crystals with localized heterogeneities. Thus, neither phenomenon is a fundamental mode of deformation. They are the result of the interactions between particular mechanical tests and particular crystals. Their general interest derives from the fact that they involve the formation of bend planes and these seem to be important to our understanding of the behavior of dislocations.

Summary

The inhomogeneities of deformation which occur at the restrained ends of zinc crystals, at tensile kink bands, and at compressive kink bands are described in terms of bend planes which are believed to consist of walls of edge dislocations. The bend plane bisects the angle between the slip directions on either side of it and contains the normal of the plane of the two slip directions. This is used to explain the migration of the bend plane through the lattice at an end restraint, the "anomalous" rotation of the lattice within a tensile kink band, and the geometric conditions which obtain during the formation of a compressive kink band.

Experiments are described in which artificial tensile kink bands were formed by transverse scratches. Scratches cause tensile kink bands in zinc crystals of a range of orientations; which side is scratched is relatively unimportant. It is concluded that tensile kink bands form in zinc if a specimen contains a region of inhibited slip. The lag of the inhibited slip planes in the reorientation process causes bending moments on either side of the inhibited planes. These lead to bend plane formation and thence to a tensile kink band.

Two new bend plane phenomena are described. One of these results when a partially cleaved crystal is elongated. The tongue-like projection resulting from the partial cleavage bends sharply away from the rest of the crystal. This phenomenon is explained by the formation of a bend plane at the base of the projection. The other new phenomenon is caused by a longitudinal scratch on a zinc crystal. Under certain geometrical conditions this causes a bend plane to form parallel to the tension axis of the crystal.

may be seen directly. In the replica process one of the phases present in the structure as-cast is converted into a translucent material, and the second phase remains virtually unaffected, permitting microscopic examination by transmitted light.

Alloys of lead and antimony were made from the chemically pure metals, cast in a sooted and pre-

Fig. 1—Chemical replica of 4 pct Pb-Sb alloy. X160. Area reduced approximately 50 pct for reproduction.

Fig. 2—Chemical replica of 12 pct Pb-Sb alloy showing a crystal of primary antimony. X2000. Area reduced approximately 50 pct for reproduction.

heated brass mold, then air cooled. A vacuum pump was used to draw the molten metal into the mold, producing a sheet 0.003 to 0.004 in. thick. By this technique foils were cast having microstructures similar to those in massive castings except that in most cases the foils were one grain thick. A smooth finish is required on the mold faces to assure ready release of the cast foil and because the specimens may not be polished after casting, owing to their thinness and softness.

The replicas were prepared by prolonged treatment of the as-cast foil specimens with the familiar acetic acid-superoxol etchant.¹ The metal foil, supported on a microscope slide or cover glass, was placed in a shallow dish containing etchant. After a period of several hours the foil was converted to a replica and removed to a slide for microscopic examination. The replica was illuminated by transmitted light and micrographs made. The replicas were also examined with the stereoscopic microscope, which clearly showed the three dimensional distribution of the two phases. Chemical replicas were thus prepared and examined for 1, 4, 9½, and 12 pct Pb-Sb alloys. The replicas are fragile and must be handled with care. It has also been found necessary to make all examinations while specimens are still moist because the translucent material becomes powdery and opaque upon drying.

As evidenced by X-ray diffraction determinations, the replicas are composed of amorphous material and metallic antimony. The white amorphous material contains lead, also trivalent and pentavalent antimony.² This is possibly a mixture of lead metantimonate with tetroxide and trioxide of antimony. The opaque material, which appears black in the accompanying micrographs, is identified by X-ray diffraction as metallic antimony.

Fig. 1 is a chemical replica of a 4 pct Pb-Sb alloy at low magnification showing the dendritic formations present in the cast metal. The translucent material is found in those areas originally occupied

by the lead solid solution. The black portions are the unattacked antimony-rich phase segregated in the interdendritic and intergranular areas. It is evident from this projection of the three-dimensional structure that the entire structure is dendritic, but in many cases the antimony is distributed across dendrite arms; the arms lie at random angles to the specimen surface; and the primary, secondary, and tertiary branches are of varying sizes. For these reasons a metallographic etch of a random cut through such a specimen will often fail to show any recognizable dendritic formation.

At low magnifications, the replica structure of the hypoeutectic alloys resembles that shown in Fig. 1. Examination at higher powers shows that segregated antimony is spheroidal in the low alloys up to approximately 6 pct Sb, and above this concentration the segregated antimony assumes more definite shapes, resembling the eutectic structure commonly seen in metallography. Primary crystals of antimony appear as the eutectic point is exceeded, as in Fig. 2, from a replica of a 12 pct Pb-Sb alloy.

It is intended to use the replica technique to investigate the effects of heat treatment, working, and aging of Pb-Sb alloys. For example, homogenized alloys should produce uniform translucent replicas containing no particles of segregated antimony; annealed specimens should show agglomeration of the antimony into discrete crystals, and the accompanying changes in the lead dendrites; Widmannstätten structure, which is difficult to demonstrate metallographically in these alloys⁴ should be rendered readily visible in the replicas.

Preferred Orientations in Iodide Titanium

by Carl J. McHargue and Joseph P. Hammond

The wire textures for cold rolled and recrystallized iodide titanium and the sheet textures for this material produced by cold and hot rolling, and recrystallization at a series of temperatures were determined. The effect of the $\alpha \rightarrow \beta$ transformation on the sheet texture was noted.

UNTIL recently it was believed that all hexagonal close-packed metals deformed by slip on the basal plane, (0001), and that rolling should tend to rotate this slip plane into the plane of the rolled sheet. The pole figures of cold rolled magnesium¹ are satisfactorily explained on this basis. There is a tendency for the $\langle 11\bar{2}0 \rangle$ directions to align parallel to the rolling direction, and the principal scatter is in the rolling direction. Zinc² has a rolling texture in which the hexagonal axis is inclined 20° to 25° toward the rolling direction. Twinning is believed to account for the moving of the basal plane away from parallelism with the rolling plane. The texture of beryllium³ places the basal plane parallel to the rolling plane with the $[10\bar{1}0]$ direction parallel to the rolling direction, and the scatter from this orientation is primarily in the transverse direction. Cold rolled textures reported for zirconium⁴ and titanium⁵ show the $[10\bar{1}0]$ directions to lie parallel to the rolling direction and the (0001) plane tilted by approximately 25° to 30° to the rolling plane in the transverse direction.

Rosi⁶ has recently reported that the mechanisms for deformation in titanium are distinctly different from those commonly reported for hexagonal close-packed metals. The principal slip plane is the prismatic plane, $\{10\bar{1}0\}$, with some slip also occurring on the pyramidal planes, $\{10\bar{1}1\}$. However, there is no evidence for basal slip. The slip direction is reported to be the close-packed diagonal axis, $[11\bar{2}0]$. In addition to the twin plane commonly reported for metals of this class, $\{10\bar{1}2\}$, Rosi found the twin planes $\{11\bar{2}2\}$ and $\{11\bar{2}1\}$, with the dominant twin plane being $\{11\bar{2}1\}$.

Information regarding the recrystallization and hot rolling textures of hexagonal close-packed metals is limited. Barrett and Smigelskas report that rolling beryllium at temperatures up to 800°C and recrystallization at 700°C produce textures not differing from the cold rolled sheet texture.³ McGeary and Lustman find that hot rolling at 850°C produces the same basic texture in zirconium as rolling at

room temperature.⁴ These investigators also report that the texture for sheet zirconium recrystallized at 650°C differs from the cold rolled orientation inasmuch as the $[11\bar{2}0]$ direction, instead of the $[10\bar{1}0]$ direction, is parallel to the rolling direction. In the case of titanium, it is not possible to deduce which direction is preferred in the recrystallized state from the pole figures presented by Clark.⁵

The purpose of this paper is to report an extensive investigation of the preferred orientations in iodide titanium. Since the deformation mechanisms for titanium are different from those commonly given for hexagonal close-packed metals, it is not surprising to find distinct differences between the textures of titanium and other metals of this class.

Materials and Methods

This investigation was carried out on iodide titanium obtained from the New Jersey Zinc Co. with an analysis as follows: N, 0.002 pct; Mn, 0.004; Fe, 0.0065; Al, 0.0065; Pb, 0.0025; Cu, 0.01; Sn, 0.002; and Ti, remainder.

The crystallinities of titanium were broken from the as-deposited bar and melted to form 20 g buttons on a water-cooled copper block in a vacuum arc-furnace. Hardness tests conducted on the material before and after melting differed by only two or three Vickers Pyramid Numbers, indicating no or insignificant contamination. The buttons were hot forged, ground, and etched to sizes and shapes suitable for the rolling schedule, and vacuum annealed at 1300°F. Specimens for determination of the wire textures were reduced 91 pct in diameter to 0.027 in. in 24 steps using grooved rolls. In order for the orientation of the central region to be studied, portions of these wires were electrolytically reduced to a diameter of 0.005 in. using the procedure described by Sutcliffe and Reynolds.⁷ The sheet textures were determined on titanium cold rolled 97 pct to a thickness of 0.005 in. A reduction of approximately 10 pct per pass was used, and the rolling direction was changed 180° after each pass.

Specimens used for determination of the recrystallized textures were annealed in evacuated quartz tubes at 1000°, 1300°, and 1500°F. The grain size of the 1000°F specimen was sufficiently small to give satisfactory X-ray patterns with the specimen stationary. However, it was necessary to scan the surface of the other recrystallized specimens. The microstructure of each annealed specimen was that of a recrystallized material. The diffraction rings all showed the break-up into spots typical of recrystallized structures.

Discussion on this paper, TP 3364E, may be sent, 2 copies, to AIME by April 1, 1953. Manuscript, April 28, 1952. Los Angeles Meeting, February 1953.

This paper represents part of a thesis by C. J. McHargue submitted in partial fulfillment of requirements for degree of Doctor of Engineering to the Graduate School, University of Kentucky.

Fig. 1—Fiber axis in iodide titanium.

In order that the orientations in titanium deformed at elevated temperatures could be investigated, annealed ingots were reduced 95 pct in thickness to 0.010 in. at 1050° and at 1450°F. The specimens were heated in air and rolled between sheets of mica to minimize heat losses. The material was reheated after each reduction, which amounted to approximately 10 pct of the sheet thickness. These specimens were etched slightly to remove the surface contamination.

The effect of the $\alpha \rightarrow \beta$ transformation on the preferred orientation was found for a specimen cold rolled 97 pct, heated 5 min at 1650°F in vacuum, and very slowly cooled.

The X-ray specimens were made in the shapes of small rods by polishing strips in a specially constructed jig and etching away the material affected by this polishing. The data for samples of larger grain sizes were obtained by shots on sheet material in a structure integrating camera.⁸ Transmission photograms were taken with molybdenum radiation (45 kv, 18 ma) and a 0.030 in. pinhole. Since titanium fluoresces under these conditions, it was necessary to use a zirconium filter between the

specimen and film. Exposures were made with the beam perpendicular to the rolling direction at 0°, 11°, 26°, 41°, 56°, 71°, and 79° to the cross direction, and with the beam perpendicular to the cross direction at 11°, 26°, 56°, 71°, and 79° to the rolling direction. Additional exposures were then made where necessary. The variations in intensity of the diffraction rings were estimated by eye with the aid of an exposure chart. Intensity readings of 0, 1, 2, and 3 were made on all specimens except those hot rolled, for which intensities of 0, 1, and 2 were used.

Discussion of Results

Wire Textures: The orientation of the cold rolled wire can be described as having the $[10\bar{1}0]$ direction, or type II digonal axis, parallel to the wire axis with all azimuthal position possible. This is shown schematically in Fig. 1a. Burgers, Fast, and Jacobs report the same wire texture for zirconium,⁹ and Morell and Hanawalt report it for Dowmetal.¹⁰

The texture at the surface and the center is essentially the same, varying only in the degree of scatter about the ideal. From a measurement of the spread of the diffraction spots,¹¹ it was found that the $[10\bar{1}0]$ direction has a spread of $\pm 6^\circ$ to the wire axis in the central region and $\pm 15^\circ$ in the surface layers.

The maxima of the diffraction rings for the recrystallized specimens were found to be split and joined by regions of lesser intensity. The average values of the maxima for the (0002), $(10\bar{1}0)$, $(10\bar{1}1)$, and $(11\bar{2}0)$ planes give the average orientation as having the $[11\bar{2}0]$ direction, or type I digonal axis, parallel to the wire axis. However, this orientation is accurately described as having strong concentrations of the basal planes tilted $\pm 11^\circ$ to the wire axis with some basal planes at all positions between these. The $[11\bar{2}0]$ direction is located so that it would be parallel to the wire axis if the basal plane

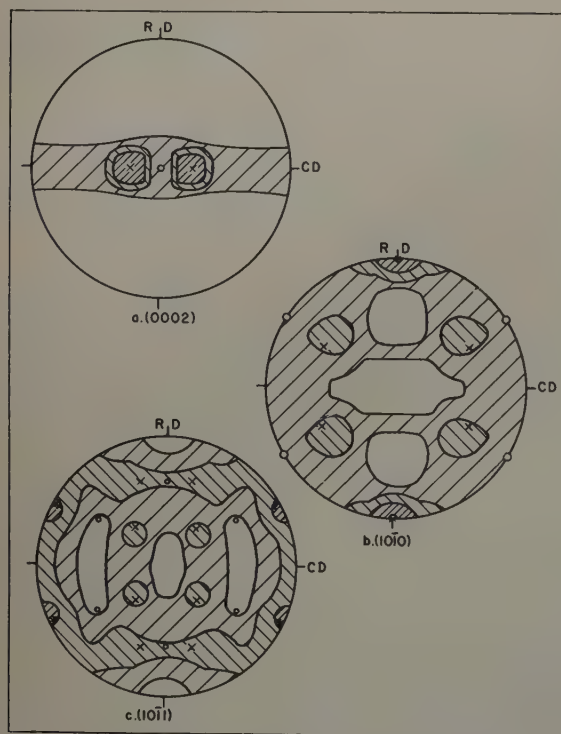

Fig. 2—Cold rolled sheet texture of iodide titanium. $\circ = (0002) [10\bar{1}0]$. $x = (0002)$ rotated 27° about rolling direction.

Fig. 3—Cold rolled annealed texture of iodide titanium. $\circ = (0002) [10\bar{1}0]$. $x = (0002)$ rotated 27° about rolling direction.

Fig. 4 (left) — Iodide titanium cold rolled 97 pct, annealed at 1300°F. • = (0002) rotated 27°, $[11\bar{2}0]$ parallel to rolling direction. α = (0002) rotated 27°, $[10\bar{1}0]$ parallel to rolling direction.

Fig. 5 (right) — Iodide titanium cold rolled 97 pct, annealed at 1500°F. • = (0002) rotated 27°, $[11\bar{2}0]$ parallel to rolling direction.

were to be rotated until parallel to the wire axis. The orientation is such that the $(21\bar{3}0)$ plane is normal to the wire axis, which is shown schematically in Fig. 1b.

Exposures on the surface layer do not show the strong, split maxima, but indicate the average position of $[11\bar{2}0]$ to lie along the wire axis with a spread of $\pm 35^\circ$. The recrystallized wire texture of zirconium⁸ has been found to be $[11\bar{2}0]$.

Cold Rolled Sheet Texture: The cold rolled sheet texture for iodide titanium is presented in Fig. 2. Fig. 2a shows that two high intensity regions are developed for (0002) planes, which correspond to rotation of approximately 27° in the transverse direction from the "ideal" orientation of (0002) $[10\bar{1}0]$ reported for other hexagonal metals. McGeary and Lustman found indications of this tilt in zirconium,⁴ and it has been reported in titanium by Clark.⁵ Fig. 2b shows that the $[10\bar{1}0]$ direction is aligning parallel to the rolling direction, and Fig. 2c confirms the selection of (0002) rotated 27° and $[10\bar{1}0]$ parallel to the rolling direction as the orientation describing the texture. Most of the spread from this "ideal" orientation is in the transverse direction.

Cold Rolled Recrystallized Sheet Texture: Fig. 3 presents the pole figures representing the orientation of the material annealed at 1000°F. These pole figures show that the cold rolled texture is retained for recrystallization at a relatively low temperature, and that there is a slight sharpening of the texture.

An investigation of material cold rolled 97 pct, and vacuum annealed at 1300°F indicates that a dual texture is present in this condition. As is shown in Fig. 4, this texture can be explained in terms of the tilted basal plane and one component having the $[10\bar{1}0]$ direction parallel to the rolling plane, and another component having the $[11\bar{2}0]$ direction parallel to the rolling direction.

The pole figures for iodide titanium cold reduced 97 pct and annealed at 1500°F, Fig. 5, are describable in terms of the basal plane tilted approximately

27° and the $[11\bar{2}0]$ direction aligned with the rolling direction.

Thus, it is seen that the texture obtained upon recrystallization depends upon the temperature of treatment. This work indicates that the cold rolled texture is retained by the material just recrystallized. However, as the temperature is increased and grain growth and secondary recrystallization take place, a new texture is produced.

The texture reported for zirconium recrystallized at 1200°F differs from the cold rolled texture by a rotation of 30° about the normal to the basal plane.⁴ Beck¹² and Kronberg and Wilson¹³ point out that there is a component of the recrystallized textures of face-centered cubic metals which corresponds to a rotation of 30° to 40° about a $[111]$ axis. The results of the present investigation lend added support to Beck's conclusion that in hexagonal close-packed and face-centered cubic metals, the reorientation upon recrystallization corresponds to a rotation about the normal of a close-packed plane.

Hot Rolled Texture at 1050°F: With the exception of beryllium³ and zirconium,⁴ there is no information on the preferred orientation produced by hot rolling hexagonal close-packed metals. These two materials retain their cold rolled textures when rolled at temperatures as high as 1475°F.

The pole figures for titanium hot rolled at 1050°F, Fig. 6, show that this texture can satisfactorily be described in terms of the "ideal" orientation (0002) $[10\bar{1}0]$. Fig. 6a shows a tendency for the (0002) planes to be tilted as in the cold rolled sheet texture, and Fig. 6b shows the tendency for the $[10\bar{1}0]$ direction to be aligned parallel to the rolling direction. The spread of the (0002) plane in the cross direction is $\pm 40^\circ$. The scatter about the normal to the rolling plane brings the $[11\bar{2}0]$ directions parallel to the rolling direction at the ends of this spread. Again, the spread is greater in the transverse direction than in the rolling direction.

That the hot rolled texture is describable in terms of the orientation (0002) $[10\bar{1}0]$ is shown by Fig. 6.

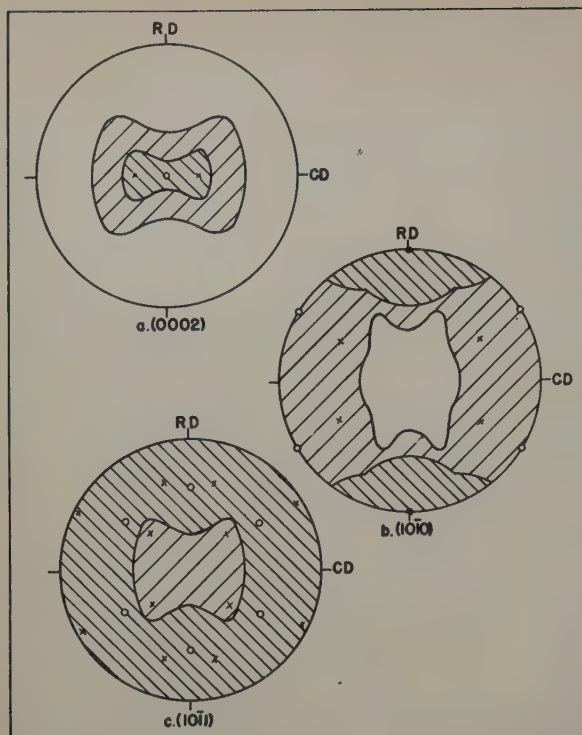

Fig. 6—Iodide titanium hot rolled at 1050°F. $o = (0002)$ $[10\bar{1}0]$. $x = (0002)$ $[10\bar{1}0]$ tilted 27°.

The orientation (0002) $[10\bar{1}0]$ is marked by "o" and this orientation tilted 27°, as in the cold rolled textures, is marked by "x." It can be seen that all regions are satisfactorily explained on the basis of (0002) $[10\bar{1}0]$. It would be possible to describe the hot rolled sheet texture as a great amount of spread about the cold rolled texture. However, it is felt, on the basis of Figs. 6b and c, that the spreads of orientations are better described as deviations from (0002) $[10\bar{1}0]$.

Fig. 7—Iodide titanium hot rolled at 1450°F. $o = (0002)$ $[10\bar{1}0]$.

Hot Rolled Texture at 1450°F: As Fig. 7 shows, the randomness of the texture in the specimen rolled at 1450°F is greater than in that rolled at 1050°F. However, the texture still retains the average position of the (0002) plane parallel to the rolling plane. There is a spread of the (0002) plane $\pm 30^\circ$ in the rolling direction and $\pm 40^\circ$ in the cross direction from this ideal orientation. In this texture, no one direction appears to be preferentially aligning parallel to the rolling direction.

Effects of the $\alpha \rightarrow \beta$ Transformation on Textures: It can be seen in Fig. 8 that a sharp texture is present after the double transformation $\alpha \rightarrow \beta \rightarrow \alpha$. This texture can be described by the 27° tilted basal plane with the $[11\bar{2}0]$ direction parallel to the rolling direction. This is the same orientation reported for iodide titanium recrystallized at 1500°F.

One specimen of cold rolled titanium sheet was cycled five times between the α and β regions, and X-ray shots were made to determine if any change

Fig. 8—Texture in iodide titanium cold rolled 97 pct, heated above the $\alpha \rightarrow \beta$ transformation temperature and slowly cooled. $o = (0002)$ $[11\bar{2}0]$. $x = (0002)$ rotated 27° about rolling direction, $[11\bar{2}0]$ parallel to rolling direction.

in the texture resulted. The only difference noted was a slight increase in the spread of the basal planes in all directions. Otherwise, the sharp texture of Fig. 8 was retained.

Summary

1—The wire texture for iodide titanium has the $[10\bar{1}0]$ direction parallel to the wire axis in the cold rolled state. Recrystallized wires have an average orientation containing the $[11\bar{2}0]$ direction parallel to the wire axis, but the actual orientation has the normal to the $(21\bar{3}0)$ plane parallel to the axis.

2—The cold rolled sheet texture is described as having the (0001) planes tilted approximately 27° in the transverse direction to the rolling plane and the $[10\bar{1}0]$ directions parallel to the rolling direction.

3—Sheets annealed in the vicinity of 1000°F retain the cold rolled textures. Those annealed at

1300°F show a component explained by the cold rolled texture, and one explained by this texture rotated 30° about the normal to the basal plane, i.e., [1120] parallel to rolling direction. Annealing at 1500°F produces only the texture containing [1120] parallel to the rolling direction and the (0002) tilted 27° to the rolling plane.

4—Hot rolling at 1050°F develops a (0002) [1010] texture with spread more pronounced in the transverse than the rolling direction. Rolling at 1450°F aligns the (0002) plane parallel to the rolling plane, but does not show a preferred direction parallel to the rolling direction.

5—The texture present after the double transformation $\alpha \rightarrow \beta \rightarrow \alpha$ is the same as the high temperature recrystallization texture.

Technical Note

Torsion Texture of 70-30 Brass and Armco Iron

by W. A. Backofen and B. B. Hundy

THE pole figure interpretation in a recent paper¹ on the torsion texture of copper was questioned in discussion,² and a simpler alternative interpretation was proposed. In the hope of reaching a positive decision in favor of one or the other, further studies were undertaken with 70-30 brass and Armco iron. This additional work has not answered all the questions about torsion textures, but the new pole figures do offer support for the original interpretation and show that the texture is more complicated than the alternative suggests.

From the previous paper,¹ the appropriate method of describing the texture in a twisted bar is known to be a pole figure plotted on a plane tangent to the surface of the bar. The axes of the pole figure are chosen to coincide with directions in the tangent plane which are parallel and at right angles to the bar axis (the longitudinal direction, L.D., and the transverse direction, T.D.), for these directions define symmetry axes of the texture. Therefore any ideal orientation that might be selected to represent the texture gives the crystallographic plane parallel to the tangent plane and the crystallographic direction parallel to the axis of the torsion specimen.

A unique texture was assumed in the original interpretation, and the four ideal orientations, (112) [111], (111) [112], (110) [001], and (112) [131], were used in its description. Of the four orientations, the first three provide possible slip directions along the direction labeled T.D. in the pole figure, which is one of maximum shear stress in a specimen being twisted. The alternative, however, simply considered

the texture to be made up of two components, one a [111] alignment along the specimen axis with a random orientation about the axis as in the wire texture, and the other a superimposed orientation (110) [001]. Experimental evidence for this simpler interpretation was derived from two observations: 1—twisting did not alter the orientation of a single-crystal torsion specimen of α brass in which an octahedral plane was perpendicular (and a [111] direction parallel) to the axis, and 2—deformation bands with approximately the (110) [001] orientation were seen to develop in the crystal during the test.

The new pole figures were obtained with a brass and an iron torsion specimen of $\frac{3}{4}$ and 1 in. gage length diameter, respectively. After annealing, polishing, and twisting, seven rods, about 0.030 in. in diameter and with different orientations, were prepared from material near the surface of each specimen; these were required for the method of constructing pole figures by using a Geiger counter as developed by Norton.³ Since the shear strain gradient in plastic torsion is linear, it was readily computed that the material supplying the brass rods had been subjected to a shear strain of about 3.2, and that supplying the iron rods had received a shear strain of about 2. All details concerning specimen design, testing procedure, rod preparation, and use of the Norton technique can be found in ref. 1. Only this procedure was followed in working out the (111) and (100) pole figures for brass, Figs. 1 and 2. However, X-ray photograms were also involved in the construction of the (110) pole figure for Armco iron, Fig. 3. The photograms were made according to the conventional transmission diffraction technique using a small sheet taken parallel to the specimen surface and etched to a thickness of about 0.0025 in. They were especially important in locating the boundaries

Fig. 1—(111) pole figure of 70-30 brass twisted to a shear strain of 3.2. Ideal orientations indicated as follows: Solid triangle, (112) $[11\bar{1}]$. Open triangle, $(11\bar{1})$ $[112]$. Double triangle, (110) $[001]$.

Fig. 2—(100) pole figure of 70-30 brass twisted to a shear strain of 3.2. Ideal orientations indicated as follows: Solid square, (112) $[11\bar{1}]$. Open square, $(11\bar{1})$ $[112]$. Double square, (110) $[001]$.

Fig. 3—(110) pole figure of Armco iron twisted to a shear strain of 2. Ideal orientations indicated as follows: Solid circle (111) $[11\bar{0}]$. Open circle (112) $[11\bar{0}]$. Vertical half-solid circle, (110) $[11\bar{0}]$. Horizontal half-solid circle, (110) $[11\bar{2}]$.

of the areas of lowest pole density. Because of the combination of methods, the pole distribution in Fig. 3 has been represented with a precision intermediate between that warranted by the counting data and photograms.

Three ideal orientations, $(11\bar{1})$ $[112]$, (112) $[11\bar{1}]$, and (110) $[001]$, have been selected for the simplest approximation of the torsion texture of brass. The first two help to account for the high concentrations of $[111]$ poles in the polar region, the central region, and, to an important extent, the peripheral region about 60° to 75° from the longitudinal direction; they also position poles reasonably well in the (100) pole figure. The (110) $[001]$ is likewise required by both pole figures, although it is not a particularly strong component of the texture. All three provide a $[110]$ slip direction along the transverse direction of maximum shear stress. There is, of course, much spread about these orientations. A possible rotation of approximately 22° around the $[112]$ direction of the $(11\bar{1})$ $[112]$ orientation is indicated with dashed lines in Figs. 1 and 2. Rotations about the $[11\bar{1}]$ and $[001]$ directions of the other two orientations are much more limited, however. Rotation about the transverse direction is also possible. The (112) $[11\bar{1}]$ can be rotated into the $(11\bar{1})$ $[112]$ and then the (110) $[001]$, although orientations between the last two are not prominent. Further rotation is possible with the $(11\bar{1})$ $[112]$ and (112) $[11\bar{1}]$ around the poles of the $(11\bar{1})$ and (112) planes. There is no need for the fourth orientation, (112) $[1\bar{3}1]$, used in the description of this texture in copper. Considering only the (111) pole figure, the texture might still be interpreted as duplex, consisting of a $[111]$ wire-like component plus the orientation (110) $[001]$; but this possibility is eliminated by the nature of the (100) pole figure.

The torsion texture of iron appears to consist of a strong alignment of $[110]$ directions along the specimen axis, which is limited in its range of orientation around the axis, with (110) $[11\bar{2}]$ superimposed. The spread of the $[110]$ alignment around the longitudinal direction might be taken as the angle between the $[110]$ pole of a (110) $[11\bar{0}]$ orientation and $[112]$ pole of a (112) $[11\bar{0}]$ orientation, or approximately 54° . It seems more reasonable, however, to rule out, or at least not emphasize the

(110) $[11\bar{0}]$ limit and replace it with something closer to (111) $[11\bar{0}]$. Then the spread would be nearer 20° , roughly the angle between $[111]$ and $[112]$ poles. By slighting the (110) $[11\bar{0}]$ orientation, fewer poles from the alignment along the specimen axis appear in the central area of high pole density, which is then accounted for by the (110) $[11\bar{2}]$ orientation. The latter orientation also places poles in the peripheral area of high intensity, and their contribution on top of that from the $[110]$ alignment explains fairly well the intensity variation in that area. Rotations about the transverse direction and an axis perpendicular to the plane of the figure are also possible here. For example, a rotation might be made about a $[110]$ direction perpendicular to the figure to convert (110) $[11\bar{2}]$ into (110) $[11\bar{3}]$. Both the (112) $[11\bar{0}]$ and (110) $[11\bar{2}]$ place a $[111]$ slip direction along the transverse direction of maximum shear stress. And again there appears to be more than a superficial difference between the torsion texture and wire texture.

A few photograms were also taken using transmission specimens prepared from two other bars of brass and iron that had been twisted and untwisted by equal amounts. These indicated that the texture established by twisting is not altered if the direction of twisting is reversed, which is the conclusion reached in the work with copper from comparison of complete pole figures.

To summarize, according to the new pole figures, the torsion texture is not the texture found in cold-drawn wire; it is a unique texture that can be described approximately by a combination of ideal orientations, but one that requires still more study before generalizations about its development, description, and correlation with flow can be made.

Forging of Arc-Melted Chromium

by H. L. Gilbert, H. A. Johansen, and R. G. Nelson

High purity electrolytic chromium plate has been hydrogen-reduced and arc-melted under inert atmosphere to give sound ingots. These ingots may be hot forged to break the as-cast structure and then worked at 500°C to finished form. An intermediate and final high temperature anneal gives best ductility and grain refinement.

THE increasing interest in refractory metals for use in high temperature gas turbines, jets, and rockets has led to great efforts in exploiting the fifth and sixth groups of transition elements. Much of the interest has centered upon production of metals that can be worked and fabricated by normal means to produce various engine parts or components having the high temperature characteristics of oxidation resistance and high creep strength required for such uses. If these pure elements do not exhibit all of the desired characteristics, it may be possible to obtain a high purity alloy that will.

Since, in all cases, development of these transition elements has depended to a large extent upon removal of oxygen and nitrogen as a means for producing ductile metal, the hypothesis has been accepted that oxygen is the normal embrittling material in a high grade electrolytic chromium metal. Various methods have been employed in an effort to remove this oxygen by direct or indirect attack.¹

Many workers have endeavored to produce pure chromium through reduction of the oxide by carbon or active metals, while others have recommended fusion electrolysis of chromium salts or reduction of these salts by active metals, such as sodium or calcium. Hydrogen reduction of the oxide or chloride and thermal dissociation of the iodide have been reported to give high purity metal.

Experimental Work

The U. S. Bureau of Mines, Northwest Electrodevelopment Laboratory, has systematically re-examined the more promising methods and developed two which produce metal having ductility at temperatures lower than heretofore described.

It has been found² that oxide-free chromium chlorides in a NaCl-KCl carrier salt may be mag-

nesium-reduced and the byproduct salts distilled off in vacuo to give a high purity chromium sponge. Fusion analysis conducted under the supervision of W. W. Horton of Knolls Atomic Power Laboratory showed the oxygen and nitrogen both to be below 10 parts per million on a selected sample. A small amount of carbon is carried over in the final metal from the chlorination and reduction steps which are carried out in graphite crucibles. This trace of carbon is not detrimental to hot ductility.

A more practical method for producing ductile metal is through hydrogen reduction of high purity electrolytic chromium. Normal electrolytic chromium will, if "developed" for a few minutes at 1100°C in high vacuum, be found by the method of Adcock³ to contain about 1 pct chromium sesquioxide (Cr_2O_3). This small amount of oxygen may be effectively reduced by hydrogen.^{2, 4}

The method employed was to crush electrolytic chromium plate in a gyratory crusher to pass 60-mesh; finer crushing appears to offer no advantage. A nitric acid leach removed the iron picked up during crushing. The leached powder was rinsed until neutral with distilled water and vacuum-dried.

Charges of chromium powder were loaded in molybdenum boats into the 2-in. diam porcelain tubes of the reduction furnace shown in Fig. 1. The system was then evacuated and checked carefully for leaks. Cylinder hydrogen was admitted through a palladium catalyst tower to convert contained oxygen to water which was removed in the phosphorus pentoxide tower. Hydrogen was added until the gasometer rose, which insured a pressure above atmospheric in the system.

Rapid circulation (25 liters per min at standard temperature and pressure) was accomplished by means of a small commercial diaphragm pump sealed in a steel box under an atmosphere of hydrogen from the furnace system so that pump leakage was no problem. The getter furnace was heated to effect initial purification of the circulating hydrogen gas. A Zr-Ti alloy (50-50 mol pct) getter that has a very high affinity for any contaminating gas present was employed. The cold trap was then filled with dry-

Fig. 3—Arc melted chromium ingots, $1\frac{3}{8}$ to 2 in. diam.

ice-acetone mixture and the reduction furnace turned on. Most of the water formed by reduction was removed from the system by this cold trap, so the metallic getter and phosphorus pentoxide traps had a long service life.

The temperature of the reduction furnace was maintained at a selected point between 1100° and 1200°C . The main getter furnace was operated at 890°C , and small auxiliary furnaces at the inlet end of the reduction tubes were maintained at a like temperature. Considerable hydrogen was absorbed by the getters when they were first exposed, but no further absorption or elimination was encountered under the conditions of operation. After 16 hr at reduction temperature, the furnace was cooled and the metal removed from the molybdenum boats. As some sintering of the chromium powder took place during reduction, it may be sized upon removal. Lumps $\frac{1}{4}$ to $\frac{1}{8}$ in. in size were found best for arc-melting purposes.

Melting was accomplished in an inert-atmosphere arc furnace shown in Fig. 2.⁵ A thoriated tungsten tip $\frac{1}{2}$ in. in diam and 1 in. long screwed into a water-cooled copper electrode holder was used. The

Fig. 4—Half section of chromium ingot, full scale. Etchant, aqua regia.

melting crucible was of pure copper approximately 2 in. ID and 4 in. long. The chromium lumps were loaded into the feed box and the furnace evacuated and backfilled with 80 pct helium-20 pct argon from a getter supply tank. The chromium was fed to the melting cup by a built-in vibrating feeder. An arc of 40 v and 800 amp (dc) will melt 750 g of chromium in 20 min. The ingots as removed from the furnace had a fairly good outer surface, but removal of $\frac{1}{8}$ in. depth on the lathe assured that no cold-shut difficulties would be encountered. Three sizes of ingots are shown in Fig. 3.

Representative analysis of the metal is as follows: Fe, 0.001 pct; Si, 0.05; O, 0.003; N, 0.002; and H, 0.005. In regard to all other metallic impurities, the metal is as pure as the best spectrographic standards available on the market today. Tungsten pick-up during melting was nonuniform and varied from none to

Fig. 5—Chromium ingot. Etchant, aqua regia. X2. Area reduced approximately 75 pct for reproduction. a (left)—As cast. b (center)—Forged 25 pct at 850°C. c (right)—Forged 25 pct, annealed 1 hr at 1200°C in hydrogen.

0.01 pct. Tungsten distribution was very random, and it may be eliminated by use of a consumable electrode of chromium.

Average ingot hardness in the as-cast condition was $R_{\text{c}} 55$ and in the annealed condition $R_{\text{c}} 46$.

The ingots were taken from the arc furnace and given a hydrogen anneal for 1 hr at 1200°C, as severe strains are set up during cooling. After annealing and scalping the ingots may be worked open or sheathed. Owing to the small size of the ingots it was preferred to sheath them in iron pipe to pre-

Fig. 6—Sheet rolled from ingot without anneal. Etchant, aqua regia. X15. Area reduced approximately 70 pct for reproduction. a (left)—As removed from sheath. b (right)—Polished and etched.

vent chilling of the chromium on contact with the cold forging hammer or rolls. Initial forging was accomplished at 800° to 850°C with moderate reductions until the cast structure was broken up. This may be followed by heavier reductions at 500°C. After the material had been reduced to final dimension, an anneal in hydrogen at 1200°C gave maximum ductility and grain refinement. This material,

Fig. 7—Swaged rod $\frac{3}{4}$ in. diam and forged and polished disk of chromium.

however, cannot be bent at room temperature without fracture.

It may be seen that this treatment resembles the techniques employed for both arc-melted vanadium⁶ and molybdenum,⁷ although in some respects the behavior of the metal is more like that of tungsten.

Fig. 4 shows a sectioned arc-cast chromium ingot and Fig. 5 the grain refinement effected by forging 25 pct at 850°C followed by a 1 hr anneal at 1200°C. If the arc-cast ingot is worked to finished sheet without an intermediate recrystallization, a very coarse, fibered structure results as shown in Fig. 6. Reductions in area as high as 93 pct have been effected by rotary swaging. As with forging and rolling, an intermediate recrystallization was beneficial in avoiding a coarse-grained product. A rod swaged at 950°C is shown in Fig. 7.

It is felt that the status of development of pure chromium metal is encouraging; but, in view of the lack of cold ductility, despite the many efforts made to overcome this condition, the possibility remains that low ductility may be an inherent property of the metal.⁸ The excellent work on beryllium⁹ has given an extruded metal with fine grain and preferred orientation having an elongation of only 5 to 10 pct in the direction of extrusion. Chromium's sister element, tungsten, seldom displays an elongation better than 6 pct except in fine wire, and there is no reason why chromium may not fall in the same class.

It is believed from the results noted herein that chromium may display the final ductility of tungsten and perhaps even reach the very useful position of molybdenum.

Conclusions

It has been found that a hydrogen-reduced electrolytic chromium powder may be arc-melted to prepare ingots for forging, rolling, or swaging to desired form. Finished forms exhibit ductility at considerably lower temperature than heretofore described. It is possible that in such condition chromium will find wider usage in high temperature applications, either pure or alloyed with other metals of equal purity.

Fig. 2—Stress-strain curves of the aluminum alloy 24S-T4 at different testing temperatures.

the specimen during straining was measured by a radial strain gage reading in ± 0.0001 in.⁵ A strain rate corresponding to a movement of the test machine head of approximately 0.05 in. per min was used for all strains. The concentric tensile testing equipment was modified for low temperature testing as previously described.

Results and Discussion

The effect of testing temperature on the stress-strain behavior of the aluminum alloy is shown in

Fig. 3—Effect of prestrain in tension at room temperature on the stress-strain curve in tension of the aluminum alloy 24S-T4 at -196°C .

Fig. 2. Although the difference between the fracture ductility at room temperature and -196°C is not nearly as large as is the case for most steels, the difference is considerably greater than has been reported for a number of other face-centered cubic metals.⁶

Prestraining the aluminum alloy at room temperature and testing at -78° or -196°C produced a lower flow stress curve than would the same total strain at the low temperature. The data obtained by testing at -196°F are shown by the curves in Fig. 3. Again, prestretching at the low temperature pro-

Fig. 4—Effect of prestrain in tension at -196°C on the stress-strain curve in tension of the aluminum alloy 24S-T4 at room temperature.

duced a higher room temperature flow curve than would an equal strain at room temperature, Fig. 4. These curves are quite like those previously obtained on 2S-O aluminum and copper.¹

The fracture stress and fracture ductility possessed by the aluminum alloy at room temperature, -78° , and -196°C after prestraining at room temperature in tension and compression are shown in Fig. 5. Room temperature tensile prestrains apparently have little effect on the low temperature fracture stress, while room temperature compressive prestrains are harmful to the fracture stress only when the magnitude of the precompression is quite large.

When the room temperature prestraining and the low temperature testing were both by tension, the dependence of retained ductility on prestrain can be described by the equation previously presented for steel:

$$\left(\frac{\epsilon_p}{\epsilon_A}\right)^m + \left(\frac{\epsilon_r}{\epsilon_R}\right)^n = 1 \quad [1]$$

where: ϵ , the maximum natural strain, is defined as the natural logarithm of the ratio of the original cross-sectional area to the final cross-sectional area; ϵ_r , the retained ductility in the second straining op-

Fig. 5 (right)—Effect of room temperature tensile and compressive prestraining on the low temperature fracture stress and ductility of the aluminum alloy 24S-T4.

Fig. 6 (below)—Effect of low temperature tensile prestraining on the room temperature fracture stress and ductility of the aluminum alloy 24S-T4.

eration; ϵ_A , the fracture ductility at the temperature of first strain; ϵ_B , the fracture ductility at the temperature of second strain; ϵ_p , the prestrain; and m and n , the material constants.

Since the retained ductility-prestrain curves are straight lines in this case, m and n are equal to one, as is the case for most of the materials investigated to date.

Small compressive prestrains at room temperature were again shown to be unarmful to the tensile ductility both at room and low temperatures. An earlier study showed small compressive prestrains to be helpful to room temperature tensile ductility⁷

and this effect probably persists even with low temperature straining, although data at sufficiently small strains were not collected.

Reversing the order of strains so that the low temperature stretching preceded the room temperature stretching again produced retained ductility-prestrain curves which were straight lines, intercepting the ordinate at the value of room temperature ductility, and the abscissa at the values of low temperature ductility, see Fig. 6. Hence the behavior is again described by Eq. 1.

Acknowledgments

The authors wish to express their gratitude to the Office of Naval Research, U. S. Navy, in cooperation with whom this work was conducted, for permission to publish these data. The authors further acknowledge with pleasure the kind help and guidance given by W. M. Baldwin, Jr., Research Professor, G. Sachs, former director of the project under whom the study was initiated, and to L. J. Ebert. A debt of gratitude is also due the General Electric Co. for supplying the liquid nitrogen used as a coolant in this study.

Effect of Alloying Elements On The Behavior of Nitrogen in Alpha Iron

by L. J. Dijkstra and R. J. Sladek

IN earlier work the effect of manganese on the general behavior of nitrogen in iron was the subject of a careful examination by Fast.¹ Part of the investigation was made, in collaboration with one of the present authors (L.J.D.), by using the internal friction method. This technique, which has been described elsewhere,² showed some significant changes in the properties of Fe-N alloys by the addition of a small amount of manganese namely:

1—Under standard conditions the maximum of the nitrogen peak in pure iron appears around 20°C and the half width is about 27°C. By addition of 0.5 atomic pct Mn a general broadening of the internal friction peak occurs. The half width is increased by about 9°C. Moreover, a shift of the maximum of about 5°C toward a higher temperature takes place, Fig. 2.

2—The precipitation of nitrogen from the supersaturated solution, measured, e.g., at 200°C, was inhibited by the addition of the amount of manganese given in effect 1.

The broadening of the nitrogen peak was confirmed in more recent work³ on samples which were prepared from Westinghouse Puron iron. The effect of manganese on the rate of precipitation, however, was much less striking than in the earlier work¹ based on Philips high purity iron.

Theory

To explain the first change in properties just referred to, effect 1, the following two assumptions were made:¹ First, every manganese atom in substitutional solid solution creates around it six interstices located between an iron and a manganese atom, as is evident from Fig. 1. These interstices, conveniently called Fe-Mn interstices, have for nitrogen a free energy level which is ΔG^* lower than the normal Fe-Fe interstices between two iron atoms. For such low concentrations of manganese as 0.5 atomic pct, the possibility that two manganese

Discussion on this paper, TP 3403E, may be sent, 2 copies, to AIME by March 1, 1953. Manuscript, May 12, 1952.

Fig. 1—Assumed modification by a manganese atom of the potential energy of a nitrogen atom in the iron lattice.

atoms will be nearest neighbors can be disregarded.

Second, it is assumed that in addition to the normal relaxation time τ_{Fe} at least one new relaxation time, $\tau_{Mn, Fe}$, enters in the phenomena which is associated with the elementary diffusion jumps between a Fe-Mn interstice and an adjacent Fe-Fe interstice. Fig. 1 gives schematically the free energy for a nitrogen atom as a function of its position along the line ABC. A tentative analysis of the nitrogen peak in a 0.5 pct Fe-Mn alloy based on these assumptions has been made in Fig. 2. The dotted curve with a maximum at 22°C is caused by jumps between Fe-Fe interstices, the dotted curve with maximum at 32°C by jumps between an Fe-Mn and an Fe-Fe interstice. The two effects added together give the dash-dot internal friction curve for the alloy. In the following these two components will be referred to as the normal peak at 22°C and the abnormal one. (The small secondary peak at

Fig. 2—Influence of manganese upon internal friction due to nitrogen in iron.

3°C is a real effect and increases very much with higher manganese content.)

If by some suitable heat treatment the nitrogen is allowed to precipitate from the solid solution in an alloy, a distinction must be made, in principle, between two different types of equilibria, since the diffusion rates of substitutional and interstitial elements are so widely different. Conditions during precipitation can be such that the alloying element participates in the diffusion, and nitrides of different alloy content from that of the matrix are formed. However, it is also possible that the alloying element does not have an opportunity to diffuse and in that case the nitride inherits its alloy content from the matrix. The terminology introduced by Hultgren will be followed in this paper and the two types of reactions will be called the ortho and the para reactions, respectively.⁴ It will also be convenient to distinguish the nitride and nitrogen-solubilities in both cases by the use of the prefixes ortho and para. In this study the para nitride is practically identical with the normal nitride in pure iron and it is clear from the picture, which was given to explain the effect of manganese, that the para solubility $C_{Fe, Mn}$ of nitrogen in the Fe-Mn alloy is higher than the normal solubility C_{Fe} of nitrogen in pure iron. The ortho solubility of nitrogen in a 0.5 pct Fe-Mn alloy must still be very small at 600°C. For, after tempering this alloy at 600°C in helium for 1 or 2 hr and quenching to room temperature, the internal friction peak has almost disappeared. A short anneal above 900°C in the γ phase is required to dissolve the ortho precipitate, and a subsequent rapid quench to room temperature reproduces the nitrogen peak to its full, original extent.

By standard methods of statistical mechanics it is

Fig. 3—Influence of chromium upon internal friction due to nitrogen in iron.

found, assuming that the temperature is not so low that saturation of the Fe-Mn interstices with nitrogen occurs, for the para solubility:

$$C_{Fe, Mn} = C_{Fe} (1 + 2c_{Mn} e^{\Delta G^*/RT}) \quad [1]$$

c_{Mn} is the atomic concentration of manganese and is assumed to be small. The factor 2 arises from the fact that per manganese atom there are six Fe-Mn interstices and per iron atom only three Fe-Fe interstices. ΔG^* is the increase in free energy on transferring a mol of nitrogen atoms from Fe-Mn sites to Fe-Fe sites (p and T constant) exclusive of the configurational part of the entropy change. The normal solubility $C_{Fe} = 3e^{-\Delta G'/RT}$ where $\Delta G'$ is the free energy of solution per mol of nitride in iron exclusive again of the change in configurational entropy.⁵ The fraction of the nitrogen atoms at the Fe-Mn interstices is $2c_{Mn} e^{\Delta G^*/RT}$.

Accepting the analysis of Fig. 2, it follows that at $T = 300^\circ K$, $2c_{Mn} e^{\Delta G^*/RT} \cong 1$ or $\Delta G^* \cong 2800$ cal per mol.

Fig. 4—Influence of molybdenum upon internal friction due to nitrogen in iron.

To explain effect 2, a third assumption appears to be necessary. In general, the rate of para precipitation is governed by three factors, namely: 1—degree of supersaturation with nitrogen; 2—diffusion rate of nitrogen; and 3—number of available potential nuclei.

Using the calculated value of 2800 cal per mol for ΔG^* and substituting this value in Eq. 1, at 200°C the solubility is increased by only 20 pct due to the addition of 0.5 pct Mn. At this temperature, there is only a slight preference for nitrogen atoms to occupy Fe-Mn interstices and therefore the diffusion rate is decreased only by a small amount. The most probable conclusion is that the large influence of manganese on the precipitation of nitrogen in this Philips iron must be a reduction, somehow, of the number of potential nucleation sites.

After cold work (e.g., 50 pct reduction in area) of the Fe-Mn alloy the internal friction peak drops rapidly by aging at room temperature. In other words, dislocations offer a much lower energy level for nitrogen atoms than the Fe-Mn interstices. This is not surprising since it is known⁶ that in pure iron the nitrogen concentration in normal solid solution in equilibrium with the nitrogen phase in the dislocations is very small.

Recent Work on Other Alloys

Recently this investigation has been extended to the alloying elements chromium, molybdenum, and

vanadium. All the alloys contained 0.5 atomic pct of the alloying element. In preparation of these alloys National Research Corp. iron was used with an oxygen content of about 0.003 pct. Furthermore, the Fe-Mn alloy was reinvestigated, this time using Westinghouse Puron iron, which has a rather high O_2 content of about 0.1 pct. In all cases the nitrogen was introduced by nitriding at 600°C for 6 min. The alloys were homogenized, unless otherwise indicated, by an anneal at 1000°C in helium for some minutes and then quenched from this temperature. After this treatment the Fe-V-N and Fe-Mo-N alloys turned out to be very unstable and even at room temperature precipitation was very rapid.

In Figs. 2 to 5 the internal friction Q^{-1} is plotted as a function of the temperature for the various alloys. The Fe-Cr alloy was not homogenized at 1000°C. The dotted curves are single relaxation peaks and are the proposed components of the total internal friction curve. In a first approximation analysis into two single relaxation peaks is indeed possible. The low temperature peak is the normal nitrogen peak at 22°C. The abnormal peak introduced by the addition of the alloying elements is

Fig. 5—Influence of vanadium upon internal friction due to nitrogen in iron.

always at a higher temperature. Apart from the theoretical picture given, the analysis in two single relaxation peaks is more or less justified by the curves of the Fe-Mo and Fe-V alloys in which indeed two pronounced peaks occur. The nitrogen peak in the Fe-Mn alloy in Fig. 2 is the exact reproduction of the corresponding peak observed earlier in the Philips iron.¹

Internal friction measurements have two disadvantages. In the first place, since the temperature is changed during the run, the ratio between the number of nitrogen atoms at Fe-Fe and Fe-alloying metal interstices is not constant and the simple analysis in two single relaxation peaks is not quite correct. In the second place, the rapid precipitation is sometimes very disturbing.

The runs of Q^{-1} vs temperature were made in the direction of increasing temperature. On cooling down from the highest measuring temperature, the Q^{-1} was much lower, especially in the Fe-Mo and Fe-V cases; apparently above 100°C para precipitation takes place during the time of measurement. Therefore elastic after-effect measurements were carried out on the Fe-Mo and Fe-V alloys at 0° and 10°C. The method and apparatus which were used

Fig. 6—Influence of molybdenum upon elastic recovery due to nitrogen in iron.

are described in a paper by Wert.⁷ The results are shown in Figs. 6 and 7. The ratio of strain over initial strain (that is, the strain while the external constant stress is applied) is plotted against the logarithm of the time which has passed since the external constant stress has been removed and during which strain recovery has occurred.

In general, the results obtained by the internal friction method are at least qualitatively confirmed insofar as mainly two relaxation times enter in the phenomena. The drawn curves correspond to single relaxation times. The normal effect resulting from jumps of nitrogen atoms between Fe-Fe interstices can be measured separately by keeping the specimen under the constant initial stress only for a time comparable to τ_{Fe} , which is therefore much shorter than $\tau_{Mn, Fe}$. These separately measured curves are shown in the lower left corner of Figs. 6 and 7. They show a discrepancy in that τ_{Fe} at 10°C is not smaller than 0°C, a discrepancy which shows up for both alloys. The accuracy of measurement is not very great for these short times. For the Fe-V alloy the abnormal effect is larger at 10°C than at 0°C. The opposite would be expected. A possible explanation is that at 0°C a state of thermodynamical equilibrium was not quite realized. In order to establish this equilibrium during cooling, the nitrogen atoms must be allowed to escape from the alloying metal atoms. They also have to diffuse over a range of the order of the average distance between the atoms of the alloying element. Because of the many uncertainties involved, more than a qualitative significance should not be attached to these results and

Fig. 7—Influence of vanadium upon elastic recovery due to nitrogen in iron.

Fig. 8—Effect of alloying elements upon precipitation of nitrogen in N.R.C. iron. Iron quenched from 1000°C before aging.

therefore a further analysis was not made of the internal friction peaks and after-effect curves.

Precipitation

In view of previous results on Philips iron, it was surprising that in this investigation it was found that the rate of precipitation of nitrogen in Puron iron was not affected at all by the addition of 0.5 atomic pct Mn. Nitrogen precipitates for equal concentrations at about the same rate in Puron iron, National Research Corp. iron, Philips iron, and the Puron Fe-Mn alloy. Apparently the high O_2 content of the latter alloy neutralizes the effect of 0.5 pct Mn. The mechanism for this effect is not clear.

Fig. 8 shows the rate of para precipitation of nitrogen at 30°C in various alloys which were all prepared from National Research Corp. iron. The specimens were homogenized at 1000°C in helium for at least 2 min and then quenched from this temperature. Since it was believed that the height of the normal component is the real measure for the degree of supersaturation, the value of $Q^{-1}_{30^\circ}$ as plotted is the height of this component at 30°C. Though no nitrogen analysis has been made, it seems that the Fe-Cr alloys behave abnormally and show a very high rate of precipitation.

Not much information is available on the ortho precipitation reaction. The following was found for the Fe-V alloy only: Tempering at 600°C for 3 min and quenching to room temperature showed a drop in Q^{-1} of about 50 pct; tempering for 45 min, a drop of about 100 pct; tempering at 700°C for 3 min was sufficient to cause a drop of 100 pct in Q^{-1} . This ortho precipitate is probably submicroscopic at 600°C, for vanadium diffuses very slowly at this temperature. The ortho nitride is stable at 700°, 800°, and 900°C, but starts dissolving at 1000°C in the γ phase. The high rate of precipitation in the Fe-Mo and Fe-V alloys at room temperature might somehow be connected with an insufficient quenching rate through the region 900° to 600°C, where a very finely dispersed ortho precipitate is formed.

Discussion

Apparently the nitrogen atom in solid solution in the body-centered cubic iron lattice is not indifferent to the kind of surrounding metal atoms. If a nitrogen atom is by some means transferred from a monoatomic gaseous state into an interstice in the body-centered cubic lattice, the lattice in the im-

mediate neighborhood of the interstice is strained. It would be expected that the strain energy is larger if the interstice is adjacent to a substitutional foreign atom which is larger than an iron atom, e.g., molybdenum and vanadium. According to Pauling,⁸ the atomic diameters of iron, manganese, chromium, vanadium, and molybdenum for a coordination number 8 are 2.46, 2.48, 2.52, 2.62, and 2.72Å, respectively. That the nitrogen atoms tend, nevertheless, to cluster around the vanadium and molybdenum atoms could then mean only that a second energy term enters which probably is connected with a redistribution of electrons between nitrogen and metal atoms. It is well known that nitrogen is rather strongly electronegative.

Smithells⁹ gives for the heat of formation at 0°K the following values:

The plus sign on the right means that the reaction is exothermal. It must be admitted that these heats of formation are not purely representative for the nitrogen-metal affinity, since the metal lattice is loosened up in the compound formation to a certain extent. This can explain the rather low value for molybdenum, which has a heat of sublimation much higher than the other metals in the table. The heats of sublimation of the latter do not differ very much. The general tendency is that, in going to lower atomic numbers in a transition series, the compound is more stable. This can be understood qualitatively from the rule that the ionization potential for the outer electrons in general decreases with decreasing atomic number in a transition series.

A comparison between heat of compound formation and relative height of the abnormal peak of the various alloys is made difficult by the rapid precipitation during the measurements. Also, strictly speaking, the maxima ought to be compared for the same temperature. Nevertheless, these data seem to indicate a definite correlation. It seems reasonable, too, that the abnormal peak in the internal friction will always appear at the high temperature side of the normal peak, since the energy barrier which must be overcome for a nitrogen atom to break away from the foreign atom will be larger than in a normal interstice. In the case of manganese, chromium, and vanadium, it is apparent that the larger the relative height of the abnormal peak, the further the latter is shifted toward a higher temperature.

Systems Zirconium-Molybdenum and Zirconium-Wolfram

by R. F. Domagala, D. J. McPherson, and M. Hansen

On the basis of metallographic analysis, incipient melting data, thermal analysis work, and X-ray diffraction, phase relationships in the 0 to 50 atomic pct alloy content were carefully resolved. Phase relationships in the higher alloy content regions were outlined. A single intermediate phase, peritectically formed, of the form ZrX_2 was established in each system. A eutectic and a eutectoid were found in the zirconium-rich region of both systems. Appreciable solubility of molybdenum and wolfram was found in β zirconium, but only a slight solubility in α zirconium.

PREVIOUS work on these systems was limited to X-ray investigations of the intermediate phases^{1, 2} and preliminary surveys of the zirconium-rich alloys.³ The diagrams presented were determined principally by metallographic, thermal analysis, and incipient melting techniques. In accordance with the Atomic Energy Commission contract requirements, phase relationships up to 50 atomic pct molybdenum or wolfram were carefully resolved, while only a limited amount of work was done to outline the 50 to 100 atomic pct alloy region.

A description and analysis of the metals used in the preparation of alloys for this study are included in Table I. A "low-hafnium" zirconium crystal bar, produced by the decomposition of a volatile iodide onto a hot filament, was employed for these studies. Westinghouse "Grade 3" crystal bar was used for all alloys. The zirconium, as received, was coated with corrosion product from a standard autoclave test by which its grade designation is determined. This was removed by a sand-blasting and HF-HNO₃ pickling technique developed by the Atomic Energy Commission. The bars were cold rolled to approximately 1/32 in. sheet, pickled for iron removal, sheared to 1/4 in. squares, washed with acetone, and stored for furnace charge.

Molybdenum sheet 0.003 in. thick, 0.001 to 0.005 in. wolfram wire, and 1/2 in. wolfram rod crushed to granular form, from Fansteel Metallurgical Corp., were used as alloying stock.

Melting Procedure

A nonconsumable electrode arc furnace identical to that described in detail by Hansen et al.⁴ was used. The source of power for melting Zr-Mo alloys was a 400 amp dc welding generator, while a 900 amp dc generator was used for preparing Zr-W alloys. Electrode tips of the same material as the alloy addition were employed in both systems, i.e., molybdenum tips were used for Zr-Mo alloys, and wolfram tips for Zr-W alloys. This precluded any possible electrode contamination during arc melting.

Ingots of 20 to 30 g of Zr-Mo alloys were melted under high purity helium in the cavity of a copper block insert in a spun copper crucible. Homogeneity

was insured by remelting all ingots four to six times without opening the furnace.

Due to the large difference between the melting points of wolfram and zirconium, direct melting of the charged metals as above generally yielded ingots containing unmelted wolfram particles. This was overcome, after many variations in technique, by melting a pure wolfram charge at high power levels (700 to 900 amp) and slowly adding zirconium to form a master alloy. Such master alloys were sectioned and remelted several times, then crushed to serve as melting stock for alloys of lower wolfram content. Master alloys containing 26, 50, 52, 70, and

R. F. DOMAGALA and D. J. McPHERSON, Junior Members AIME, are Assistant Metallurgist and Supervisor of Physical Metallurgy Research, respectively, and M. HANSEN, Member AIME, is Chairman, Metals Research Dept., Armour Research Foundation of Illinois Institute of Technology, Chicago.

Discussion on this paper, TP 3378E, may be sent, 2 copies, to AIME by March 1, 1953. Manuscript, April 11, 1952. Philadelphia Meeting, October 1952.

This paper represents a portion of the work on an Atomic Energy Commission-sponsored project, Contract No. AT(11-1)-149, "Phase Diagrams of Zirconium-Base Alloys."

Fig. 1.—Partial diagram of the Zr-Mo system.

90 pct W served for the preparation of all the Zr-W alloys. Calculated weights of zirconium were melted with granules of the analyzed master alloy to yield the desired compositions. Alloys containing up to 50 pct W were arc melted in a copper block insert eight times without opening the furnace, while alloys richer in wolfram were melted ten times in a heavy-wall copper crucible. No unmelted wolfram was detected in any of the alloys prepared in this manner.

Annealing Treatments

Previous studies^{4,6} have shown that Vycor and quartz bulbs are suitable for containing specimens of highly reactive alloys of titanium or zirconium during annealing treatments. Vycor was employed for temperatures up to 1100°C, while quartz bulbs were used above this temperature. Evacuated bulbs were employed at temperatures up to 950°C, but for higher temperatures a partial pressure of argon was admitted to the bulb before sealing. This partial pressure was controlled to produce 1 atm of pressure at the temperature of treatment, in order to balance external pressure. Molybdenum sheet 0.003 in. thick was used as a liner in bulbs scheduled for treatments above 1200°C. These liners served to protect the specimens from direct contact with the bulbs and gave physical support to the bulb walls. All annealing treatments except homogenization were carried out in glazed porcelain tubes in electrically heated furnaces. Resistance alloy-wound furnaces were used up to 1250°C, but for higher temperatures a small Globar tube furnace was employed. Temperature control, in general, was $\pm 3^\circ\text{C}$, but more precise control was achieved for many anneals. Homogenization treatments were carried out in a box-type Globar furnace, with a temperature control of about $\pm 10^\circ\text{C}$. A control sample of pure zirconium was included in each bulb of isothermally annealed specimens. At the conclusion of an anneal, specimens were quenched by breaking the bulb under water.

Solidus Determinations

A high temperature vacuum-induction furnace was used for the determination of solidus temperatures. A description of the unit, details of operation, and temperature calibration have been given.⁴ The technique employed was to heat an alloy of given composition until visual signs of melting were observed, then quench a series of specimens of the same alloy content at approximately 25°C intervals below the temperature of observed melting, and examine them metallographically for evidences of incipient melting.

Thermal analysis was used to check the eutectic temperature in the Zr-Mo system, but was not generally applicable in the present work because of the high temperatures involved. The equipment and techniques employed have been described.⁴

Zr-Mo System

The chemical analyses of alloys prepared for the determination of phase relationships in this system are included in Table II. Table III lists the annealing treatments employed.

Zirconium-rich alloys containing from 0.2 to 28 pct Mo were reduced by cold pressing from 54 to 1 pct, depending upon alloy content, homogenized at 1150°C for 70 hr, and then cold rolled from 75 to 5 pct, prior to isothermal annealing treatments. All other alloys were used in the arc-cast condition.

The phase relationships for the 0 to 50 pct Mo region are presented in Fig. 1, and the entire diagram is shown in Fig. 2. Fig. 1 includes most of the experimental points necessary for the construction of the diagram; some points were omitted for clarity. Preliminary anneals for various times at 700°, 800°, and 900°C indicated that after 250, 150, and 50 hr, respectively, no changes occurred in the relative amounts of phases present in 3, 9, and 16 pct Mo alloys. The results of this program were used to schedule appropriate times for annealing treatments.

It should be noted that a preliminary investigation was undertaken in order to establish the temperature of the allotropic transformation, $\alpha \rightleftharpoons \beta$, in "Grade 3" zirconium crystal bar. Specimens from five random bars, after cold pressing, homogenization and cold rolling, were annealed at approximately 850°, 860°, 870°, 880°, and 890°C followed by water quenching. Two phase ($\alpha + \beta$) structures were observed in certain of the specimens for quenching

* Analyzed for zirconium, molybdenum by difference.

temperatures between 851° and 868°C. Apparently, then, because of impurities, this grade zirconium transforms over a range of temperatures close to the ideal transition point. The value 862°±5°C, reported by Vogel and Tonn,⁶ was adopted for construction of the diagrams, but it is certain that this departure from ideality must cause corresponding departures from true binary equilibrium in the very dilute alloys.

The eutectic at 31±1 pct Mo and 1520°±15°C was located by the microscopic examination of several as-cast, incipient melting, and thermal analysis specimens in this region. The temperature was fixed as a result of several heating and cooling curves for an alloy of the eutectic composition, as well as by incipient melting. Fig. 3 shows the eutectic structure in a 30.7 pct Mo alloy, quenched from 1535°C in the incipient melting furnace.

Examination of isothermally annealed specimens showed the solubility of molybdenum in β zirconium to decrease from 22 pct at the eutectic level to 7.5±1 pct at the eutectoid temperature, 780°C. Figs. 4 and 5 represent 20.7 and 22.1 pct Mo alloys, respectively, quenched from 1480°C. A typical retained β structure is evident in the former, while $\beta + \text{ZrMo}_2$ phases are present in the latter structure. Figs. 6 and 7 represent 9.6 and 11.9 pct Mo alloys, respectively, quenched from 900°C. The former is 100 pct β , while the latter contains ZrMo_2 . The β phase was retained on quenching alloys containing more than 5 pct Mo, but transformed to acicular α (martensite) in alloys of lower molybdenum content.

The eutectoid decomposition: $\beta \rightarrow \alpha + \text{ZrMo}_2$ proceeds very slowly in this system. The eutectoid level was determined by examination of hypereutectoid alloys annealed at temperature increments of 15°C. The eutectoid level and the sluggishness of the decomposition are illustrated in Figs. 8 and 9. The former illustrates the retained $\beta + \text{ZrMo}_2$ structure observed after annealing a 14.5 pct Mo alloy at 790°C for 610 hr. The latter figure shows the 15.7 pct Mo alloy quenched from 775°C after 380 hr. In this specimen, a small amount of the β adjacent to proeutectoid ZrMo_2 crystals has decomposed. The metastability of β was detrimental to accurate position-

Fig. 2—Zr-Mo system.

ing of the eutectoid composition, but the value presented, 7.5 pct, undoubtedly is within ±1 pct of the equilibrium value. Eutectoid decomposition in hypoeutectoid alloys was never observed.

The solubility of molybdenum in α zirconium is less than 0.18 pct at all temperatures. Fig. 10 shows a 0.18 pct Mo alloy quenched from 775°C after 240 hr. The α plus metastable β phases are present.

The intermediate phase, ZrMo_2 , is formed by the peritectic reaction: Melt + molybdenum-rich solid solution $\rightarrow \text{ZrMo}_2$. The peritectic configuration and the composition of the liquid entering into the peritectic reaction are illustrated in Figs. 11 and 12. A 57.8 pct Mo arc-melted alloy is shown in the former figure. Only two phases, ZrMo_2 and β , are present. Fig. 12, a 59.0 pct Mo alloy, illustrates the initial appearance of the third phase, molybdenum-rich solid solution, as primary crystals. The composition of the peritectic melt is therefore between 57.8 and 59 pct Mo. Heat treatment in the incipient melting furnace brought the peritectic reaction nearly to completion in a 65.4 pct Mo alloy. ZrMo_2 and a small amount of β were present in this structure, supporting the designation of the phase as ZrMo_2 (stoichiometrically, 67.78 pct Mo).

An X-ray pattern of -325 mesh powder from a 57.8 pct Mo alloy was made, using filtered, characteristic $\text{CuK}\alpha$ radiation. Indexing of the pattern indicated that the intermediate phase has a cubic lattice, C15 (MgCu_2 type) with the lattice parameter, $a = 7.59\text{\AA}$. This is in agreement with Duwez and

Fig. 12—59.0 pct Mo alloy, as-cast. Primary molybdenum-rich solid solution, peritectic walls of ZrMo_2 and β matrix. Comparing this with Fig. 11 shows that the composition of the peritectic liquid must lie between 57.8 and 59 pct Mo. Etchant: 3 pct HNO_3 + 2 pct HF in water. X750.

necessary for the construction of the diagram are included in the former figure. The chemical analyses of Zr-W alloys are given in Table V. Table VI lists the annealing treatments employed.

Prior to the isothermal anneals, alloys containing 0.5 to 26 pct W were reduced up to 32 pct by cold pressing, homogenized 45 to 70 hr at 1200°C , and cold rolled up to 20 pct. The amount of reduction by cold working was, of course, dependent upon the wolfram content. The Zr-W system is similar in all structural features to the system Zr-Mo.

The eutectic between β and ZrW_2 was positioned at 18 pct W and $1650^\circ\pm 15^\circ\text{C}$ after examining alloys containing 0.5 to 26 pct W in the as-cast condition and quenched in the incipient melting furnace. The eutectic composition is believed to be accurate within ± 2 pct W. The solubility of wolfram in β zirconium decreases from a maximum of 8 pct at the eutectic temperature to about 0.5 pct at the eutectoid temperature, 850°C . Figs. 15 to 18 position the $\beta/\beta + \text{ZrW}_2$ phase boundary at two temperature levels.

Fig. 15, a 3.6 pct W alloy quenched from 1460°C , contains only transformed β , while a 5.3 pct alloy quenched from the same temperature displays $\beta + \text{ZrW}_2$ (Fig. 16). Fig. 17 is a 0.49 pct W alloy quenched from 950°C , illustrating a transformed β structure, and a 1.3 pct W alloy, quenched from the same temperature, Fig. 18, contains ZrW_2 at the boundaries of transformed β grains. No clear retained β structures were observed in this system. Rejection of very fine ZrW_2 particles from β solid solution, even on quenching, masked most structures so that this point was impossible to determine with certainty.

The eutectoid decomposition of β into $\alpha + \text{ZrW}_2$ was placed at $850^\circ\pm 15^\circ\text{C}$. Difficulty was experienced in interpreting some structures because of the low alloy content of the eutectoid (0.5 pct W) and its proximity to the transformation "range" of unalloyed zirconium. Three-phase structures such as that shown in Fig. 19 indicated the proximity to the eutectoid temperature. This is a 1.3 pct W alloy quenched from 850°C .

Fig. 13—Partial diagram of the Zr-W system.

Fig. 14—Zr-W system.

Fig. 17—0.49 pct W alloy quenched after annealing at 950°C. Transformed β solid solution. Etchant: 20 pct HNO_3 + 20 pct HF in glycerin. X250.

Fig. 18—1.3 pct W alloy quenched after annealing at 950°C. Transformed β solid solution plus ZrW_2 crystals. Etchant: 20 pct HNO_3 + 20 pct HF in glycerin. X250.

The solubility of wolfram in α zirconium is considerably less than 0.5 pct (the most dilute alloy prepared) at all temperatures. A single intermediate phase, peritectically formed, was detected in this system. Claassen and Burgers² have reported this phase to be ZrW_2 (stoichiometrically, 80.13 pct W) having a cubic structure (C15 type) with the lattice parameter, $a = 7.61\text{\AA}$. Figs. 11 and 12, illustrating the peritectic formation of ZrMo_2 , are characteristic of the structures observed in a 48.5 and a 52.3 pct W alloy, respectively. The 48.5 pct W alloy contained only ZrW_2 and β phases, while primary dendrites of wolfram-rich solid solution were observed in the latter alloy. Accordingly, the composition of the peritectic melt has been placed at 50 pct W.

Because of the considerable difference in wolfram

Fig. 19—1.3 pct W alloy quenched after annealing at 850°C. $\alpha + \beta + \text{ZrW}_2$ structure characteristic of alloys quenched from this temperature, indicating the proximity to the eutectoid level. Etchant: 20 pct HNO_3 + 20 pct HF in glycerin. X500.

YZW80-795	82.8	2175	2075

content between the peritectic melt and the intermediate phase, and the difficulty in equilibrating the resultant three-phase alloys, nearly single-phase ZrW_2 structures were not obtained. Therefore, X-ray patterns were not made to check the structure of this phase, and the work of Claassen and Burgers has been accepted as valid.

A limited investigation of wolfram-rich alloys indicated that less than 10 pct Zr is soluble in wolfram.

The incipient melting data are presented in Table VII. The results of these studies placed the β - ZrW_2 eutectic temperature at $1650^\circ \pm 15^\circ C$ and the peritectic at $2175^\circ \pm 25^\circ C$.

Summary

The Zr-Mo and Zr-W phase diagrams were carefully determined to 50 atomic pct alloy content. A limited amount of work was done to outline the phase fields in the molybdenum and wolfram-rich regions of the diagrams. Alloys were melted in a nonconsumable electrode furnace using Grade 3 iodide zirconium crystal bar as a base material. These highly reactive alloys were prepared and heat treated under protective atmospheres to prevent contamination.

Zr-Mo: The important features of this system include:

1—Only one intermediate phase, $ZrMo_2$ (ideally 67.78 pct Mo), exists. It is formed by the peritectic reaction: Melt (58 pct Mo) + Mo-rich solid solution $\rightarrow ZrMo_2$ at $1880^\circ \pm 20^\circ C$.

2—A eutectic between β solid solution and $ZrMo_2$ exists at 31 ± 1 pct Mo and $1520^\circ \pm 15^\circ C$.

3—The limit of solubility of molybdenum in β

zirconium is about 22 pct at the eutectic temperature.

4—A sluggish eutectoid decomposition of β into $\alpha + ZrMo_2$ occurs at 7.5 ± 1 pct Mo and $780^\circ \pm 5^\circ C$.

5—The limit of solubility of molybdenum in α zirconium is less than 0.18 pct at all temperatures.

6—Less than 10 pct Zr is soluble in molybdenum.

Zr-W: This system is similar to the Zr-Mo system, and includes the following features:

1—A single intermediate phase, ZrW_2 (ideally 80.13 pct W), exists. It is formed by the reaction: Melt (50 pct W) + W-rich solid solution $\rightarrow ZrW_2$ at $2175^\circ \pm 25^\circ C$.

2—A eutectic between β solid solution and ZrW_2 occurs at $1650^\circ \pm 15^\circ C$ and 18 pct W.

3—The limit of solubility of wolfram in β zirconium is about 8 pct at the eutectic temperature.

4— β decomposes into $\alpha + ZrW_2$ eutectoidally at about 0.5 pct W and $850^\circ \pm 15^\circ C$.

5—The solubility of wolfram in α zirconium is less than 0.5 pct at all temperatures.

6—Less than 10 pct Zr is soluble in wolfram.

Acknowledgments

The authors wish to thank the Atomic Energy Commission, sponsors of this work, for permission to publish this paper. Special thanks are due to C. E. Lundin, who supervised the preparation of alloys, C. A. Johnson, who was responsible for the metallographic work, and W. Rostoker, for interpretation of the X-ray patterns.

Technical Note

Sintering of Ultrafine Ferromagnetic Powders

by N. I. Ananthanarayanan and J. F. Libsch

A LITERATURE survey¹⁻⁴ of sintering metal powders and powder compacts indicates that studies have so far been confined primarily to the latter stages of sintering in relatively coarse powders. Presumably this is due to the difficult techniques associated with studies of the early stages of sintering. Recent experimental and theoretical investigations⁵⁻⁹ on the preparation and the magnetic properties of ultrafine ferromagnetic powders suggest the possi-

bility of following the sintering process from a very much earlier stage than has previously been considered.

It is now well-known that ferromagnetic powder particles which are below a critical size behave as single domains and exhibit permanent magnet qualities characterized by a very high coercive force. When the same particles are fully sintered, the coercive force decreases to very low values corresponding to those of the solid metal. Thus the coercive force appears as a sensitive parameter which may be measured to study the early stages of sintering. To determine the feasibility of this technique, experi-

N. I. ANANTHANARAYANAN is a graduate student and J. F. LIBSCH, Member AIME, is Associate Professor of Metallurgy, Dept. Metallurgical Engineering, Lehigh University, Bethlehem, Pa. TN 119E. Manuscript, May 2, 1952.

Fig. 1—Variation of coercive force with sintering temperature for ultrafine iron powder compacts.

ments have been initiated on the sintering behavior of ultrafine iron powders.

The present experiments were restricted to powders prepared by the low temperature reduction of finely divided jeweller's rouge, in purified hydrogen. The rouge used contained 98 pct iron oxide and 2 pct SiO_2 , and consisted of particles predominantly one micron or less in size. It has been found that of the powders thus prepared in the temperature range of 600° to 1000°F for 200 min of reduction time and for a hydrogen flow of about 1.5 cu ft per hr per g of oxide, the powder reduced at 700°F exhibited the maximum coercive force, viz., 560 to 600 oersteds. This powder was chosen for the experiments reported, because it provided the maximum variation of the coercive force between the "loose" and fully sintered states. Particle size of the reduced powder was estimated by the electron microscope, X-ray diffraction, and nitrogen adsorption methods, yielding an average particle size of 200 to 250 A.U. Since the powders were pyrophoric and were, therefore, covered with liquids like acetone for protection from oxidation during their subsequent handling, they were pressed wet into bars of approximately $1\frac{1}{4} \times \frac{1}{8} \times \frac{1}{8}$ in. at a single pressure of 40 tons per sq in. The compacts, first evacuated in the sintering chamber to remove all traces of protecting liquid present, were sintered in a stream of dry hydrogen for a period of 2 hr at various temperatures between 450° and 1800°F. The coercive force of the sintered compacts was then measured using a high-H permeameter of the Sanford and Bennet type.¹⁰

The coercive forces of the sintered compacts plotted as a function of sintering temperature are shown in Fig. 1. It may be noted: 1—that up to a temperature of 1000°F there is a very gradual fall of coercive force with sintering temperature; 2—that in the relatively narrow range of temperature between 1000° and 1600°F there is a strikingly rapid diminution of coercive force from about 500 to about 70 oersteds; and 3—that the rate of decrease of the coercive force at the higher temperatures is once again gradual.

The initial slow decrease of coercive force with sintering temperature indicates that little sintering has occurred and that the single domain character of the particles constituting the specimen has been essentially preserved. The relatively narrow range of sintering temperature in which the coercive force undergoes an abrupt diminution marks the exces-

sive formation of domain boundaries between the individual particles by sintering. The subsequent slow decrease of the coercive force with increasing sintering temperatures is to be associated with elimination of the porosity, the slow progress of which, as is well-known, is characteristic of the latter stages of sintering. The final value of the coercive force reported at the highest sintering temperature used, e.g., 25 oersteds at 1800°F, is still high compared with that of massive iron, because of the presence of impurities and the low density obtained, e.g., approximately 4 g per cc.

Any interpretation of the data in terms of the sintering mechanism must recognize the presence of some SiO_2 and some oxygen in the pressed compacts before sintering, since the SiO_2 was present in the rouge used for reduction and reduction of the oxide is not complete at 700°F. The presence of these impurities may have a pronounced influence and would tend to retard sintering by interfering with the formation and lateral growth of point bonds. With pure iron powders completely reduced, the temperature range of sudden decrease in coercive force would be expected to shift to the left.

From the data presented, it appears that the temperature range representing a sudden decrease in coercive force may be an indication of appreciable sintering and the consequent formation of excessive domain boundaries. While the initial and final values of the coercive force may depend chiefly upon the particle size, the purity and possibly the porosity of the powder particles, it is believed the temperature range of sudden decrease in coercive force will depend primarily upon the factors which influence the initiation and progress of sintering. A shift in this temperature range may conceivably be used to show the influence of various nonmetallic films on the powder particles, pressing pressure, and sintering atmosphere upon the initiation and progress of sintering. Experiments to determine the usefulness of this new criterion are presently underway.

The use of coercive force as a parameter for sintering behavior is, of course, limited to ferromagnetic materials. However the electrical resistivity of metals and alloys, another structure-sensitive property, is also known to undergo a large change below a critical size, as evidenced by the many and scattered investigations that have been reported on thin metal films.¹¹ The measurement of electrical resistivity might perhaps form a still more general approach to the study of building up polycrystalline aggregates from ultrafine powders by the powder metallurgy technique.

Measurement of Internal Boundaries in Three-Dimensional Structures By Random Sectioning

by Cyril Stanley Smith and Lester Guttman

It is shown, from a study of geometric probabilities, that the average number of intercepts per unit length of a random line drawn through a three-dimensional structure is exactly half the true ratio of surface to volume. Since the surfaces can be internal or external, the area of grain boundary or of the interface between any two constituents in a microstructure can be measured. Other metric relations are tabulated that may be of use in studies of the microstructure of polycrystalline, cellular, or particulate matter generally.

IN many fields of scientific investigation the structure of cellular aggregates or random arrays of discrete particles imbedded in some matrix is observed on a two-dimensional section and inferences are drawn therefrom as to the real structure in three dimensions. The biologist's microtome slice, the petrologist's thin section, and the metallurgist's plane polished and etched sections are common examples, although the problem is a general one. Scientists have commonly limited their thinking to the same dimensionality as their structures, and the few attempts that have been strictly three-dimensional in character have been laborious and noteworthy.

From a metallurgical standpoint it is often of considerable importance to know, in addition to the volume fraction of two or more components in an alloy, the amount of two-dimensional interface between crystals. Such grain boundaries (which may separate either two identical crystals differing only in orientation or two crystals differing in structure, and possibly also in orientation) have a determining factor upon the mechanical behavior. It is at these boundaries that melting commences, that stress-induced corrosion occurs, and that various precipitates (harmful or otherwise) first appear. The boundary is doubtless of equal importance in nonmetallic crystalline aggregates such as rocks, ceramics, and concrete, and the biologist is deeply concerned with the area of cellular membranes. Many synthetic cellular foams involve similar structural problems. The very term structure usually implies the presence of interfaces and a complete understanding of structure involves nothing but an analysis of the geometrical, metrical, and topological relations between the various interfaces (zero, one and two-dimensional) that exist in a three-dimensional structure. Even systems lacking sharp physical interfaces often have interrelated gradients of composition or velocity (as cored crystals or turbulence cells) in which a neutral surface can be treated as a two-dimensional interface.

C. S. SMITH, Member AIME, is Director and L. GUTTMAN is associated with the Institute for the Study of Metals, University of Chicago, Chicago.

Discussion on this paper, TP 3430E, may be sent, 2 copies, to AIME by March 1, 1953. Manuscript, April 16, 1952.

In an earlier paper by one of the authors¹ the question of cell shape was considered in terms of simple topological principles without regard to physical dimensions. The determination of the actual size of grains in two dimensions is carried out in a routine fashion in innumerable metallurgical laboratories (see, for example, the ASTM standard methods of grain size determination²), though this is done merely to check the uniformity of a product and has no relation to the actual three-dimensional shape or size of the grains. Some authors have discussed the three-dimensional problem but only on the basis of assumptions as to idealized grain shapes.³⁻⁵ Quantitative measurements of microstructures to obtain the volumetric relations of various phases have been carried out by petrographers for many years and are of increasing popularity among metallurgists.⁶

The present paper will show how, on the basis of no assumptions other than randomness of sectioning (usually realizable in experiment), it is possible to learn a great deal about the three-dimensional structure. The relations to be derived will generally be used on random arrays of cells or other particles, although they are equally applicable to ordered arrays and even to isolated objects of complex shape provided that suitable random sections can be made.

Total Area of Interfaces in a Sample

Consider a typical microstructure of a single-phase polycrystalline metal, such as that shown schematically in Fig. 1. The plane cross section shown contains a network of lines which subdivides the area into two-dimensional cells. The lines, of course, represent merely the intersection of the two-dimensional plane of sectioning with the two-dimensional interfaces between adjacent three-dimensional cells. The structure also contains points at which two or more lines intersect; in three dimensions the points are, of course, lines.

In the more general case there may be in three dimensions isolated particles surrounded by a single interface without contact with others, and both two and one-dimensional features which do not necessarily connect with others. On the two-dimensional section these will appear as areas delineated by a closed line (as at *a* and *b*, Fig. 2), as isolated lines

Fig. 1 (left)—Plane section through a polycrystalline body.

Fig. 2 (right)—Plane section through a polycrystalline body containing isolated particles (sectioned at *a* and *b*), isolated surfaces (sections *c* and *d*), and lines sectioned at *e*.

not intersecting others (as at *c* and *d*), or just as isolated points (*e*).

Relations in Two Dimensions: The two-dimensional structure itself will be considered first. It is possible by the use of a map measurer to determine the total length of line in any given area isolated for study. However, this can be done more easily by making use of the probability of intersection of one line with another randomly applied. It is intuitively apparent that the number of intersections will depend in a simple manner on the length of line, and that there will exist a relationship between an area and the length of random line traversing it. By combining these relations it is possible to obtain the ratio of line to area as a simple direct function of the average number of intercepts per unit length of an intersecting straight line (or grid) randomly applied to the structure.

We begin by rederiving the well-known solution to Buffon's "needle" problem:* a line segment of

* Czuber (ref. 7) pp. 84-92. None of the other relations derived in the equations to be given are to be found in their most general forms in the standard works on geometrical probability which have been consulted. Czuber's theorem III (p. 113), IV (p. 115), Problem XXI (p. 116) and Problem III (p. 178) contain formulas similar to ours, but are essentially restricted to convex plane curves. Czuber apparently did not realize that the concept "probability of intersection" could be generalized to "average number of intersections," and thus apply to non-convex curves.

Note added Sept. 30, 1952: After this paper was submitted, there appeared a communication by Campbell and Tomkeieff (*Nature* (1952) 170, p. 117) containing results similar to ours, in which, however, the unnecessary restriction to convex bodies is still made. L. A. Santaló has derived two-dimensional formulas like ours and has stated that the extensions to three dimensions are obvious. Cf. (a) *Abh. Math. Sem. Hansischen Univ.* (1940) 13, pp. 284-294; *Math. Reviews* (1941) 2, p. 13. (b) *Revista Union Mat. Argentina*, (1943) 9, pp. 145-164; *Math. Reviews* (1947) 8, p. 170.

length *l* falls at random on a plane array of parallel lines spaced a distance *d* apart (Fig. 3). What is the probability that the line segment intersects one of the lines (*l* ≤ *d*)?

The probability is clearly the average length of the segment projected on the normal to the array, divided by the distance between the lines, i.e.:

$$p = \frac{\bar{l}_{proj}}{d}$$

Fig. 3—Diagram to illustrate probability of a line intersecting a grid.

Since all directions of the line segment have equal *a priori* probability:

$$\bar{l}_{proj} = \frac{2}{\pi} \int_0^{\pi/2} l \cos \theta d\theta = \frac{2l}{\pi} \quad [1]**$$

** From this follows an interesting property of all simple plane figures that are not concave. Since each element of the perimeter appears twice within the average projected width, the latter must be exactly $1/\pi$ of the perimeter. It is also to be noted that the average linear intercept across such a figure is $\pi \times \text{area/perimeter}$.

and:

$$p = \frac{2l}{\pi d} \quad [2]$$

If an irregular plane curve is placed at random on the same array, there will in general be *N* intersections; the average value, \bar{N} , can be obtained from Eq. 2 as follows. Divide the curve into short segments of length Δl , each of which is nearly straight. The probability that any one of these segments intersects the array is $p_1 = 2\Delta l/\pi d$, and the product of this with the number of segments is the average number of intersections:

$$\bar{N} = p_1 \cdot \frac{l}{\Delta l} = \frac{2l}{\pi d} \quad [3]$$

l is the total length of the curve. Even though the segments are connected by being parts of the curve, each takes random positions and orientations as the curve as a whole does, hence the additivity of the number of intersections.

In dealing with a given area of a microstructure it is often useful to express the results in terms of ratio of length to area. Consider the limited area***

*** This figure intentionally contains features impossible in any real microstructure to emphasize the independence of the relations on anything but the existence of one and two-dimensional features.

in Fig. 4 crossed by a grid of spacing *d*. If *d* is small, or if a coarse grid is applied many times at random to a fixed area, the total length of grid line, *L*, is *A/d*. Combining with Eq. 3, the following useful relation results:

$$\frac{l}{A} = \frac{\pi}{2} \frac{\bar{N}}{L} \quad [4]$$

In using this relation it is not necessary to utilize a well-ruled grid of parallel lines, but any array of lines repeatedly applied to the structure in a random fashion is satisfactory provided that a sufficient number of intersections is counted. If the structure itself is random, a single line (not necessarily straight) of sufficient length is adequate. Generally, however, it is preferable to use a grid and to apply this successively at various angles between 0° and

180° selected to give the desired total number of counts.

There are no limitations whatever as to the validity of Eq. 4 except for the critically important requirement of randomness.

Relations in Three Dimensions: Consider now the relation between a random two-dimensional section and the three-dimensional structure it represents. Fig. 5 depicts an irregular solid body with closed surface, intersected by a set of parallel planes. This is analogous to the two-dimensional case of Fig. 3. The sections visible in the two-dimensional planes will have an area A and a perimeter of length l . The averages of these, \bar{A} and \bar{l} , are desired for all possible positions of the body. Let the distance between the planes again be d , and assume for simplicity that the surface does not intersect more than one plane at a time. The position of the surface can be specified by the distance z of a fixed point on it from one of the planes, and its orientation by three

Fig. 4—Isolated area of a two-dimensional structure traversed by a grid of lines.

angles, denoted by ω for brevity. The area of the section is a function $A(\omega, z)$ whose average value is:

$$\bar{A} = \frac{\int d\omega \int dz A(\omega, z)}{\int d\omega \int dz}$$

For a fixed orientation, $A(\omega, z)dz$ is the element of volume of the solid enclosed by the surface. Hence as z varies between the limits $(0, d)$,

$$\int_0^d dz A(\omega, z) = V$$

a result independent of orientation.

$$\bar{A} = \frac{V}{d} \quad [5]$$

There is no restriction on the shape of the surface or on the connectivity of the solid enclosed by it: The distinction between "inside" and "outside" determines what is to be counted as contributing to the cross-sectional area, and conversely.

Consider now a plane figure which intersects one of the planes of the stack in a line of length l (Fig. 6). Again, the average length of intersection is:

$$\bar{l} = \frac{\int d\omega \int dz l(\omega, z)}{\int d\omega \int dz}$$

For a fixed orientation, $l dz$ is just the element of surface of the figure, projected on a plane which includes the intersection and which is normal to the stack of planes, i.e.:

$$l dz = dS \sin \theta$$

Fig. 5—Diagram to illustrate probable area of intersection of a particle with a set of parallel planes.

where θ is the angle between the normal to the figure and the normal to the stack. Hence, the integration over z gives just the total surface area projected on this vertical plane. The only orientation angle ω which must be specified is θ , and:

$$d\omega = \sin \theta d\theta$$

The range $(0, \pi/2)$ for θ clearly covers all possible orientations, so that:

$$\bar{l} = \frac{S \int_0^{\pi/2} \sin^2 \theta d\theta}{\int_0^{\pi/2} \sin \theta d\theta \int_0^d dz} = \frac{\pi S}{4d} \quad [6]$$

This result is not restricted to plane figures, since any surface can be approximated by plane elements. As before, these elements take random positions and orientations when the figure as a whole does so, and since the contributions to the surface and to the length of intersection are additive, Eq. 6 holds for any surface, however complex.

By combining Eqs. 5 and 6:

$$\frac{\bar{l}}{\bar{A}} = \frac{\pi}{4} \frac{S}{V} \quad [7]$$

Fig. 6—Diagram illustrating probable length of intersection of a plane figure with a set of parallel planes.

Fig. 7—Intersection of grid of lines with a particle.

This result, being independent of d , means that the stack of parallel planes is no longer needed, and that it is possible to average line length and area of the sections of any solid by a plane oriented and placed at random.

It is desired to apply Eq. 7 to a solid such as a polycrystalline metal, in which the interest is specifically in the internal surfaces (grain boundaries). If the solid is macroscopically homogeneous, the quantity S/V will be a "property" of the specimen in the sense of having the same value for sufficiently large regions, whatever their location. Then it will be possible to obtain its value for the entire specimen from measurements of the average value, \bar{l} , of line length in many equal areas, A , randomly located. If the solid is isotropic as well, a single section will suffice if it is extensive enough, but in general both random directions and random locations of the sections would have to be established.

It is not necessary to measure \bar{l} directly, since Eq. 4 provides a means of determining the length of an irregular curve by random intersections with another of known length. Since the \bar{A} and \bar{l} of Eq. 7 become the A and l of Eq. 4, then

$$\frac{S}{V} = \frac{2\bar{N}}{L} \quad [8]$$

Note that d does not appear in this equation. It means simply that the internal surface in a unit volume of a solid is exactly twice the average number of intersections per unit length of lines drawn at random in the solid.

Eq. 8 can be deduced more directly in another way. Consider a grid of parallel lines spaced a distance d apart in directions normal to each other and to the lines. An irregular solid is placed in the grid (Fig. 7); the average number, \bar{N} , of intersections of its surface with the lines and the average length of line intercepted, \bar{L} , are desired. The position and orientation of the solid are described by the coordinates (x, y) of one of its points in the plane perpendicular to the lines, and by a set of angles, ω , as before. Then:

$$\bar{L} = \frac{\int d\omega \int dx \int dy L'(x, y, \omega)}{\int d\omega \int dx \int dy}$$

For fixed ω , $L' dx dy$ is the volume element, and $\iint L' dx dy = V$, independent of angle. Hence:

$$\bar{L} = \frac{V}{d^2} \quad [9]$$

a result which is intuitively obvious. For a plane figure, whose largest diameter is $\leq d$, the probability of intersection is just the ratio of its average projected area to the area per grid line, i.e.:

$$p = \frac{\bar{A}_{proj}}{d^2}$$

But:

$$A_{proj} = S \cos \theta$$

and:

$$\bar{A}_{proj} = \frac{\int_0^{\pi/2} S \cos \theta \sin \theta d\theta}{\int_0^{\pi/2} \sin \theta d\theta} = \frac{S}{2} \quad [10]^\dagger$$

[†] From Eq. 10 a result of interest for non-concave solids in general can be deduced; on the average, each element of the total surface, S , of such a solid appears twice within the same projected area, so that, for convex solids only:

$$\bar{A}_{proj} = \frac{S}{4} \quad [10a]$$

This theorem has been attributed to Cauchy, but the original publication has not been located.

whence:

$$p = \frac{S}{2d^2} \quad [11]$$

Table I. Properties of a Two-Dimensional Structure

Item	Equation No. in Text	Property	Contiguous Cells of Same Type	Separate Cells Not Sharing Boundaries
1		Average area of cell	$\frac{A}{M}$	$\frac{L_a d}{M_a}$
2		Average linear intercept	$\frac{L}{N}$	$\frac{2L_a}{N_a}$
3	4	Ratio of length of line to total area (perimeter to particle area in separate cells)	$\frac{\pi N}{2L}$	$\frac{\pi N_a}{2L_a}$
4		Ratio of average perimeter of cell to average linear intercept*	$\frac{N^2 A}{\pi M L^2}$	$\frac{\pi N_a^2 d}{4 M_a L_a}$
5		Area fraction of phase α		$\frac{L_a}{L}$

* This dimensionless shape factor is rigorously applicable only if all cells are convex and if there are no lines except those constituting the perimeter of some cell. It is 4 for circles, $24\sqrt{3}\pi$ for regular hexagons, $16/\pi$ for squares, and $36/\pi\sqrt{3}$ for equilateral triangles. (See double asterisk note to Eq. 1.)

Table II. Properties Determinable Rigorously from Random Two-Dimensional Sections of Three-Dimensional Structures

Item	Equation No. in Text	Property	Contiguous Cells	Separate Cells or Particles Not Sharing Boundaries and with No Internal Features
1		Average cross section of cell or particle	$\frac{A}{M}$	$\frac{L_a d}{M_a}$
2		Average linear intercept	$\frac{L}{N}$	$\frac{2L_a}{N_a}$
3	7, 8, 13	Ratio of area of total two-dimensional features to total volume (surface to volume ratio for separate particles)	$\frac{4l}{\pi A}$ or $\frac{2N}{L}$	$\frac{2N_a}{L_a}$
4	14	Ratio of length of total one-dimensional features to total volume (edge to volume ratio for separate particles)	$\frac{2n}{A}$	$\frac{2n}{L_a d}$
5	15	Ratio of total one-dimensional to total two-dimensional features (edge to surface ratio for separate particles)	$\frac{\pi n}{2l}$ or $\frac{nL}{NA}$	$\frac{n}{N_a d}$
6		Volume fraction of particles of α phase		$\frac{L_a}{L}$

A = total area of two-dimensional section examined.
 l = total length of linear features in area A .
 M = total number of grains, cells or particles seen in area A .
 n = total number of points (grain corners) seen in area A .
 M_a = number of separate particles of constituent α .

L_a = total length of line traversing area occupied by constituent α .
 L = total length of line in grid of area A applied to structure.
 d = spacing of lines in grid.
 N = number of intercepts of grid lines with linear features of structure.
 N_a = number of intercepts of grid lines with lines bounding constituent α .

More generally, for any surface:

$$\bar{N} = \frac{S}{2d^2} \quad [12]$$

S being the total surface area, including internal or re-entrant positions. As before, this follows from the possibility of building any surface from plane elements, each of which takes up random positions and orientations as the surface as a whole does so, and to each of which Eq. 11 applies.

Combining Eqs. 9 and 12, then

$$\frac{\bar{N}}{L'} = \frac{S}{2V} \quad [13]$$

The grid is no longer necessary, and if, as for Eq. 8, the number of intersections with random lines of total length L is measured, it may be seen that Eq. 13 leads to the same result.

The three-dimensional structure also may have one-dimensional cells (lines) either defining the limits of various two-dimensional surfaces or existing by themselves without any relation to such. The

number of intersections, \bar{n} , with a set of planes d apart (randomly applied) can easily be shown by the methods used in deriving Eqs. 3 and 5 to be $\lambda/2d$, λ being the true length of the line. Since the total area of the intersecting planes and the volume considered are related as before,

$$\bar{n} = \frac{\lambda A}{2V} \quad \text{or} \quad \frac{\bar{n}}{A} = \frac{\lambda}{2V} \quad [14]$$

This gives directly by the observation of points in random plane sections the length of line in a given volume. This relation can be combined with Eq. 2 dealing with the ratio of line to surface to give directly (on the basis of purely two-dimensional measurements) the ratio of line to surface, which is:

$$\frac{\lambda}{S} = \frac{\pi}{2} \frac{\bar{n}}{l} = \frac{\bar{n}}{A} \frac{L}{N} \quad [15]$$

Use of the Relations

It should be noted that in all of the preceding, L , A , and V are gross values determined by the area

Table III. Properties Determinable on Assumption That Particles Are of One Size and Spherical

Item	Equation No. in Text	Property	Contiguous Cells of Same Type	Separate Particles Not Sharing Boundary

2	16	Number of particles per unit volume of whole sample	$\frac{\pi LM^2}{4NA^2}$	$\frac{\pi LM_a^2}{2N_a A^2}$ or $\frac{\pi M_a^2}{2N_a Ld^2}$
3		Average surface area per grain or particle	$\frac{8}{\pi} \left(\frac{NA}{LM} \right)^2$ (See note*)	$\frac{8}{\pi} \left(\frac{N_a d}{M_a} \right)^2$

* Note: If the average surface area of the grains considered as separate polyhedra is desired, this number must be doubled.

selected for study, and the mere counting of intersections within this area gives the total amount of surface and of line. There are no assumptions whatever except that of randomness of sectioning. If the structure itself is random and isotropic a single surface—or even a single line—will suffice provided only that the number of counts is large enough to give satisfactory statistics; if the structure is anisotropic, true averages will only be obtained by combining counts on sections which are randomly oriented and placed.

The factor N/L is the reciprocal of the average linear intercept through the cells assuming them to be convex. Though metallurgists have frequently used this average linear intercept as an index of grain diameter, the fact that it is so simply and exactly related to the ratio of surface to volume seems not to have been previously noticed.

It is possible to experimentally measure on an actual two-dimensional section the total number of intercepts, N , with grain boundaries of a traversing line of a known total length, L (the total being made up of many lines, a distance d apart, repeatedly crossing the area being examined^{††}) as in Fig. 4; the

^{††} In practice d is either the spacing of a grid of parallel lines used for counting or the total area studied divided by the total length of traversing line (i.e., $d = A/L$). Experimentally, it is convenient to use a grid of circular outline which can be applied repeatedly at different orientations to portions of an extended microstructure. The value of A/L is then constant and needs no further measurement. If the specimen area itself is limited and falls always entirely with the grid, its true area is used, and the equivalent L derived from the grid spacing. Counting is easier if, instead of a fine grid in a few orientations, a grid is used of fairly coarse spacing, applied frequently and in many orientations in order to get the necessary counts. To avoid repetition at 180° rotation the grid lines should be displaced from exact symmetry or the grid itself should be moved around randomly within the area available for study. A grid 20 cm diam with lines 1 cm apart has been found satisfactory. With structures on the scale normally used for an 8x10 in. micrograph 12 applications 15° apart give an adequate number of counts.

The counting of intersections or cells is most easily recorded by a counting pencil of the type used by bacteriologists, and may be either electrically or mechanically operated. Instead of using a photograph, measurements may be also made directly on a specimen under the microscope, the grid being either projected optically upon the sample or being laid on the focusing screen of a projection apparatus. A large specimen area may easily be covered in this way by appropriate traversing at properly distributed angles. It would be possible to use a counter operated by a photocell and to record all necessary data automatically, provided that clearly defined boundaries are obtainable and there are no extraneous details in the specimen that would affect local light intensities.

The measurement of the length of linear intercept is most readily obtained by the use of a linear integrating stage of the type used by petrographers, such as that of Hurlburt,⁸ or Wentworth,⁹ or the hydraulic one designed by one of the authors.¹⁰ It is possible to replace these rather elaborate devices by a simple inexpensive stage for point-counting,¹¹ but this seems to be both more tedious in operation and, unless an extremely large number of points are counted, less accurate.

number, M , of particles appearing in section on the whole surface of known area, A ; the number, n , of points ("grain corners") seen in a section. If more than one phase is present, it is possible to measure for each phase the number of intercepts (N_a) of the traversing line with its boundaries, the total length of line (L_a) traversing that phase, and the number (M_a) of α -phase particles seen on an area A .

The results of the preceding paragraphs have been rewritten consistently in terms of the quantities just defined and collected in Tables I and II. The tables also include immediately derivable expressions for the cross-sectional area of a particle or cell, A/M , and the average linear intercept through a particle, L/N . Two sets of formulas must be used, corresponding to the case of one phase or of separate phases. In the latter case, in order to study each phase separately, the actual area of each, $L_a d$, must be used instead of A , and the linear intercept becomes $2L_a/N_a$. If there is more than one phase present the volume percentage of any given phase is precisely determined by the ratio L_a/L_{total} in the now well-known method of linear analysis.⁹

Shape-Dependent Properties

In all of the foregoing it was not necessary to make any assumptions as to the form of the structures under consideration. Therefore very general results were obtained which are true for all shapes, but which cannot for just that reason give information about shape-dependent properties. In this class of properties are the average "caliper diameter" and the average projected area of a particle, neither of which can be measured on a cross section. In this class also, therefore, is the particle volume, which is equal either to the product of the caliper diameter in a certain direction and the average sectional area normal to it, or to the product of the area projected on a certain plane and the average linear intercept in the perpendicular direction.

For the special case of a spherical particle there are simple relations between those properties that are accessible from a plane section and those that are not. If a random arrangement of identical spheres is sectioned, the number of spheres P_a in a volume V can be found from:

$$\frac{P_a}{V} = \frac{\pi}{2} \left(\frac{L}{N_a} \right) \left(\frac{M_a}{A} \right)^2$$

in the notation of the previous section.[‡] It may be

[‡] Relations identical with these have been independently derived by both F. N. Rhines and R. Teitel. These authors discuss the use of these relations in determining grain size or particle size and the distribution of these. Apparently the effect of departures from the rigorous requirement of sphericity is not serious in practice.

assumed that this formula holds approximately for grains which are not too elongated in any particular direction, and which fill space, and thence the volume per particle, V_p , as the reciprocal of the above, may be calculated:

$$V_p = \frac{4}{\pi} \left(\frac{N}{L} \right) \left(\frac{A}{M} \right)^2 \quad [16]$$

the factor two coming from the sharing of boundaries in the present case. By combining Eq. 16 with earlier results, the formulas appearing in Table III are obtained. It should be stressed that these formulas, unlike those in Tables I and II, must be systematically in error, and that they should be used with caution.

Summary

The extent of one and two-dimensional internal boundaries of a solid (e.g., grain edge length and grain boundary area in a polycrystalline metal) can be calculated from measurements on plane sections.

The method involves counting the number of intersections of the boundary with planes of known area or lines of known length oriented and located at random. For example, if a line randomly intersects an array of surfaces or interfaces, then the average number of intersections per unit length is exactly equal to one-half the ratio of surface area to volume. The accuracy of the results is only statistically limited and does not depend on assumptions of shape or isotropic arrangement. True randomness of section is essential.

It is possible to obtain the length or area of a particular kind of feature, for example, the area of interface between any two phases, as well as the surface to volume ratio for any constituent, in addition to the total interface measurements.

It is not possible to derive the volume of the average cell from measurements on two-dimensional sections except on the assumption of a constant shape

and size. Formulas derived for identical spheres are tabulated and may be of some use.

Retained Austenite Determinations by X-Ray Methods

by B. L. Averbach

THE determination of retained austenite by X-ray diffraction uses the following relationship:^{1,2}

$$P_{\alpha} = \text{constant} \cdot RV_{\alpha} A(\theta) \quad [1]$$

where: P is the diffracted power from phase α ; R , the calculated intensity factor; $A(\theta)$, the absorption correction; θ , the diffraction angle; and V_{α} , the irradiated volume of phase α

For a flat sample making a glancing angle ϕ with the incident beam the absorption correction is calculated as:^{*}

^{*} The absorption correction in ref. 1 erroneously contained an extra $\sin \phi$ in the numerator. This error did not influence the results quoted since experimental absorption corrections were used in the retained austenite determinations.

$$A(\theta) = \frac{1}{\mu} \frac{\sin(2\theta - \phi)}{\sin(2\theta - \phi) + \sin \phi} \quad [2]$$

where μ is the linear absorption coefficient.

Beu³ has proposed that the computed absorption correction be combined with the constant and that the experimental observation of the absorption correction used in the original method be eliminated. This procedure is permissible only if: 1—There is no preferred orientation in the sample, and 2—The geometric requirements have been met precisely.

If these conditions are not met the validity of the determination is questionable. Unfortunately the necessary conditions must be tested experimentally for each determination, and this is done most easily by observing whether the apparent absorption has the form of Eq. 2. In practice it may be convenient to plot P/R vs the parameter $\sin(2\theta - \phi)/[\sin(2\theta - \phi) + \sin \phi]$ to obtain straight lines for the ap-

parent absorption correction. Deviations from straight lines indicate either that the sample has not been positioned correctly or that the relative intensities are incorrect.

Geiger counter spectrometer methods also have been used successfully for retained austenite determinations. In the usual spectrometer arrangement the sample makes equal angles with the incident and diffracted beams ($\theta = \phi$); thus the absorption correction is simply $\frac{1}{2}\mu$ and independent of θ . The retained austenite is then easily calculated from integrated intensity measurements on austenite and martensite lines. If the austenite content is not too low and if excessive fluorescence is not encountered it is possible to use filtered radiation and a recording spectrometer. The integrated intensities are then proportional to the areas of the diffraction peaks.

For lower austenite contents the following technique was used: A bent quartz monochromator and a Geiger counter spectrometer are employed. The monochromatic radiation is focused on the front slit, and the counter slit is made broad enough to include the entire line. A series of readings are taken in the vicinity of the diffraction peak. The highest reading includes the diffraction line plus background. The background is obtained from the average of several readings on each side of the peak. The integrated intensity is obtained by subtraction. CrK_{α} and FeK_{α} have been used for such determinations. This technique has been found to be as sensitive and as accurate as the photographic methods.

In the spectrometer methods the ratio austenite/martensite may be obtained from readings on austenite and martensite lines and the application of Eq. 1. It is also possible to use external standards and to obtain the austenite contents from measurements on the austenite lines alone. The small correction for carbides then becomes unnecessary. The best standards are probably samples with known

Regarding Sigma Phase Formation

by David S. Bloom and Nicholas J. Grant

IN recent reports, Sully¹ and Beck and coworkers² have advanced hypotheses concerning the formation of the σ phase. Both of these hypotheses are based on Pauling's theories of the electronic configuration of the elements of the first transition group. Sully considered that the number of electrons which can be absorbed in filling electron "holes" is the factor which determines whether or not the σ structure can form. Beck suggested that the presence of a certain concentration of electron "holes" is the controlling value.

It can be shown that a similar criterion can be developed without making reference to Pauling's theories. Table I shows the elements of the first transition group and the incidence of the σ structure in the binary systems of these elements according to the data presently available. Also appended is the number of electrons considered to exist in the 3d-4s levels of these elements. If the atomic percentages for the σ phase are listed as shown in Table II, and if the number of electrons in the 3d-4s levels per atom is calculated for the σ boundary values, the results are as shown in the last column. It can be seen that the numerical values are all in the vicinity of 7 electrons per atom. This is true also for the ternary Cr-Mo-Ni σ phase, which occurs in a system in which none of the binary compositions are known to develop the σ phase. In the Fe-Mo binary, the high temperature σ phase, which occurs at a composition of 50 atomic pct of each element, also yields a value of 7 electrons per atom.

From inspection of Tables I and II, it develops that any series of sequential numbers which is assigned to the elements under consideration will result in the numbers pertaining to σ compositions grouping themselves around one specific number. It does not follow, however, that this random number necessarily has physical significance. Such a point has already been discussed by Hume-Rothery.³

One interesting point develops from this study, however, and that is the position of manganese with reference to the other elements and to the σ phase. In the system used here, the formation of σ phase is associated approximately with the value of 7 electrons per atom, which is also the number of electrons per atom that manganese has. Manganese, it will be recalled, exists in three different crystal forms, none of which are the usual, simpler metallic forms; on the other hand, elements just to the left of manganese (in Table I) generally have lower coordination-number structures (body-centered cubic) than do elements to the right of manganese (face-centered

cubic). The contribution to a complex crystal structure by the interalloying of elements from opposite sides of manganese is significant in that the σ phase is formed in binary systems including one element from each side of manganese, with manganese capable of participating with both sides.

It is indeed an interesting coincidence that manganese, with 7 electrons per atom, solidifies in complex crystal forms, and that when alloys of the transition elements are made which have seven 3d-4s electrons per atom, they, too, tend to assume a complex crystal form.

From the above, it might be deduced that the study of the σ phase might be advanced by a critical examination of the element manganese and how its structure is affected by small additions of elements which change the 3d-4s electrons per atom number. The role of atom size would also be of interest in σ formation.

Accelerated Solidification in Ingots: Its Influence on Ingot Soundness

by Edgar Marburg

Most ingots complete solidification vertically rather than transversely. This conclusion is based on complete solidification patterns of big-end-up and big-end-down ingots developed from dumped and split ingots. New mechanisms for segregation in ingots are proposed. Internal soundness in ingots is found to depend upon adequate width of vertical core.

ALTHOUGH it has long been recognized that the internal soundness of ingots is principally dependent on the process of solidification, knowledge of this process is still only fragmentary. The mechanisms causing the several types of segregation in ingots, which mechanisms are necessarily related to the solidification process, are not well understood. In absence of a better conception of the solidification process, it seems hardly surprising that mold design varies widely. Guiding principles for mold design are needed. At stake in the improvement of ingot quality are not only improved properties of steel but also appreciably higher yields of sound steel, which would considerably decrease manufacturing costs.

In the present study, following a general description of the several types of segregation in ingots, Fig. 1, complete solidification patterns of a big-end-up and a big-end-down ingot, including the zones of accelerated solidification, have been reconstructed. In both ingots, a core of vertical solidification extends from the base cone to the hot-top junction. Based on the finding that ingots complete solidification vertically rather than transversely, as has been previously assumed, new mechanisms for segregation in ingots are proposed.

Internal soundness in ingots is found to depend upon the width of the vertical core, which in turn depends principally upon the width to height (w/h) ratio of the ingot. Solidification patterns of ingots are of three general types: 1—those in which vertical solidification does not reach the top, 2—those in which vertical solidification just reaches the top of the ingot, and 3—those in which vertical solidification reaches the top some time before transverse solidification would reach the middle of the ingot, so that a vertical core of definite width at the top of the ingot is developed. Axial defects vary characteristically with the solidification pattern. Examples of ingots of each type are presented.

Dumped ingot data reported by Nelson¹ have been used in developing families of curves of transverse

and vertical solidification, and in deriving the effect of the w/h ratio upon the solidification pattern. Photographs of many ingots split at Homestead and at Duquesne Works, United States Steel Co., as well as those published by the British Iron and Steel Institute,² have been studied and analyzed. In the interest of brevity, only typical ingots of each type or classification from the above sources have been reproduced.

Segregation in Ingots

Segregation in ingots falls into three principal classifications: 1—lamellar segregation, as revealed in sulphur prints (Figs. 2 and 3); 2—zone segregation, or broad variations in composition; and 3—interdendritic, or microsegregation. The last class, of minor importance, is not considered here.

When liquid metal cools, according to the theory of differential or selective solidification,³ metal of relatively high purity selectively solidifies first. Liquid segregates (principally carbon, phosphorus,

Fig. 2—Sulphur print of 23x23 in. ingot, AISI 1040 steel. Ladle analysis: C, 0.41 pct; Mn, 0.90; P, 0.016; S, 0.021; Si, 0.24. Ingot split at Gary Works.

and sulphur) diffuse inwardly at definite rates.²⁻⁴ But solidification also progresses at definite rates that decrease inwardly. Hence segregation does not extend far into the liquid, but is restricted to a narrow layer of liquid metal immediately adjacent to the face of solidification.^{2,5} The width of this layer and its concentration of segregation increase inwardly. The several types of segregation in ingots and prevalent theories as to their mechanisms are discussed briefly below.

V Segregation: V segregation, Fig. 1, is a lamellar type of segregation revealed on sulphur prints as imperfectly developed V's centered on the vertical axis. Generally of maximum intensity in the upper portion of an ingot, V segregation may extend well below mid-height, Fig. 3. Ingots of intermediate sizes (15 to 25-in. width) are more subject to this defect than are either smaller or larger ingots. V segregation is less pronounced in big-end-up (Fig.

Fig. 3—Sulphur print of 25x25 in. ingot, AISI 1040 steel. Ladle analysis: C, 0.45 pct; Mn, 0.71; P, 0.022; S, 0.037; and Si, 0.20. Ingot split at Homestead Works.

2) than in big-end-down (Fig. 3) ingots. In large ingots, V segregation occurs normally well below the hot-top junction, separated from the latter by a zone of clean sound steel, Fig. 4.

The mechanism proposed by the Heterogeneity Sub-Committee of the British Iron and Steel Institute²—that, in the final stages of solidification, the contraction of the ingot causes segregates to be

Fig. 4—Sulphur print of 52 in. diam ingot, AISI 1040 steel. Ladle analysis: C, 0.45 pct; Mn, 0.66; P, 0.019; S, 0.029; Si, 0.21. Ingot split at Homestead Works.

drawn downwardly from the sinkhead—fails to account for the clean zone mentioned above. Nor does it afford an explanation of the lamellar arrangement of V segregation.

Hultgren⁴ suggests that V segregation results from the entrapment of segregated liquid metal between dendrites in the completion of solidification transversely. In absence of refill metal in final stages of solidification, the unsupported dendrites sag. Sagging plus contraction in cooling, according to Hultgren, cause the V shape of axial segregation. As applied to ingots that do complete solidification transversely (Figs. 22a and 23a), this explanation appears to be sound. As will be discussed later, however, it is not applicable to ingots that complete solidification vertically.

Negative Segregation: In a roughly cone-shaped zone in the lower middle portion of ingots (Fig. 1), segregating elements occur in less than average concentrations. This region is referred to as the zone of negative segregation. The deficiency in segregating elements decreases upwardly to approximately mid-height in an ingot, at which level the steel attains an average or ladle composition.

As segregation normally increases inwardly, the zone of negative segregation in ingot interiors has been difficult to explain. In an attempt to do so, the

theory of random nucleation of crystals was proposed speculatively.² According to the random-nucleation theory, crystallites of high purity nucleate, or generate, in the liquid metal in the interior of an ingot. Being of greater density than the surrounding liquid metal, these crystallites purportedly descend to build up a zone of high-purity metal in the lower middle portion of an ingot.

Several considerations make acceptance of the theory of random nucleation of crystals difficult. First, the liquid metal in an ingot quickly attains the liquidus temperature and remains at this temperature until just before solidification occurs, when it drops sharply.^{5,7,8} Second, according to Stokes' law, the rates of descent of crystallites in liquid metal would be so slow that they could not descend the required distance in the available time.⁹ Third, macroetches of ingots show no evidence of a cone of crystals caused by the piling up of descending crystallites. In the 29x66-in. semikilled ingot (Fig. 17), for example, the equiaxed crystals are restricted to a well-defined vertical core above the base cone. If crystals descend in the liquid metal, crystals in the lower middle portion of an ingot should be larger than those above; the reverse is typical, Fig. 5.

In a re-appraisal of their theories some years after they were first proposed, the Sub-Committee on the Heterogeneity of Steel Ingots of the British Iron and Steel Institute held it more probable that the zone of negative segregation occurred as a result of ascent of less pure components away from it than that it was caused by the descent of high-purity crystals into it.⁶

Inverted-V Segregation: Inverted-V segregation is also a lamellar type of segregation, which appears in split ingots as one or a series of discontinuous

crease of ingot size, their intensity, unlike that of V segregation, does not vary greatly. In large ingots they flare outwardly near the top to form a bottleneck, Figs. 4 and 24 to 26. In ingots in which such a bottleneck occurs, V segregation is restricted to the region just below the bottleneck, Fig. 4. For present purposes, lines of inverted-V segregation have been differentiated as to whether they are inner or outer lines, Fig. 1.

No satisfactory explanation of inverted-V segregation is found in the literature. According to one theory,² it results from the ascent of segregates along the face of solidification. Another⁹ envisages periodic descent of crystallites, which causes segregates to be swept upwardly in successive waves.

The view is sometimes expressed that lines of in-

verted-V segregation are internal cracks resulting from cooling stresses. Examinations of fractured ingots at Homestead Works, United States Steel Co., have shown that these "lines" are actually narrow zones containing a network of fine dendrites, which indicates that layers of liquid metal were entrapped and solidified with an insufficiency of refill metal. To have been entrapped as a liquid, the metal must have had a lower temperature of solidification than the surrounding metal; that is, it must have been segregated.

Experimental Dumping of Big-End-Up Ingots

In experiments conducted under the supervision of the Metallurgical Department at Homestead Works, six 32x32-in. big-end-up ingots of 2 pct Ni steel were dumped at various intervals from 34 to 150 min after pour. Photographs of the split ingots appear in Figs. 6 to 8. The ladle analysis of the steel was: C, 0.83 pct; Mn, 0.77; P, 0.014; S, 0.024; Si, 0.18; Ni, 2.08; and Cr, 0.15.

The tapping temperature was 2885°F; the pouring temperature 2730° to 2680°F. The mold temperatures were not measured but were reported to be within the range (300° to 400°F) used in normal practice at Homestead Works. The mean mold-wall thickness was 7.75 in., which includes one-third depth of 3/4-in. corrugation. Measurements of thickness were made from the outside of corrugations to the depth completely solidified. This is a close approximation of the depth from the centroidal plane of the corrugations to the mean depth of partially solidified metal at the face of solidification.

No completely solid ingot of the above composition was split. In Fig. 9 is a macroetch of an ingot of this size of 1020 steel.

Transverse Solidification: The depths of solidification as measured in the upper portions of ingot Nos. 1 to 5 (Figs. 6 to 8), which portions are of uniform thickness, are tabulated and plotted in Fig. 10. The equation of a straight-line representation of the five points is $d = -0.50 + 0.93\sqrt{t}$, where d is the depth in inches and t the time in minutes. Thus, initial transverse solidification occurred according

Fig. 10—Transverse solidification in Homestead Works' 32x32 in. ingot.

Fig. 11—Vertical solidification in Homestead Works' 32x32 in. ingot.

to the Chipman-FonDersmith equation,¹⁰ $d = -C + k\sqrt{t}$.

* This equation is a modification of Feild's equation, $d = k\sqrt{t}$.¹¹ The negative constant, $-C$, signifies that the curve intersects the abscissa to the right of the origin of coordinates. Dumped ingot data^{1,10,12} (Fig. 10) support the Chipman-FonDersmith equation. Experimental data presented by Bishop, Brandt, and Pellini⁷ indicate that the negative constant in the Chipman-FonDersmith equation increases with superheat.

The face of solidification on the right-hand side of ingot No. 6, Fig. 8b, is not parallel to the side of the ingot. This is evidence of accelerated transverse solidification, which will be discussed later. The depths of solidification at 48 and 72-in. heights in ingot No. 6 have been plotted, Fig. 10.

Vertical Solidification: To allow for the zone of partial solidification, $\frac{1}{2}$ in. has been added to measured heights of complete solidification vertically. The assumed face of vertical solidification in ingot No. 6, which face was gouged by the burning flame, has been represented by a dashed line, Fig. 8b. The measured heights of vertical solidification in all of the ingots are tabulated and plotted in Fig. 11.

The secondary cavity between h_1 and h_2 in ingot No. 5 and the extensive porous zone below this cavity are clearly abnormal. Excessive jarring of the ingot during overturning may have resulted in flash solidification of the liquid metal.** It remained to

** Similar flash solidification has been observed in the interiors of small laboratory ingots that have been jarred excessively in overturning.

decide which height to measure: 1—the base of the wide cavity, h_1 ; 2—that of the narrow cavity, h_2 ; or 3—the height, h_3 , of completely solid metal. As the last point, h_3 , conforms with the pattern established by the other four points, Fig. 11, much more reasonably than does either of the other two points, it was used.

The completed curve of vertical solidification, OCV (Fig. 11), then, consists of two portions, OC and CV, the two intersecting at a wide angle VCD. The significance of this shape will be discussed later.

Effect of Ingot Width on Rates of Transverse and Vertical Solidification

Nelson¹ reported data from dumped 13x13 and 17x17-in. ingots of high-carbon electric furnace steel cast in molds of slightly less and slightly greater than 4-in. mean wall-thickness, respec-

tively. Nelson's data for transverse and vertical solidification are related below to those for the 32x32-in. ingot.

Transverse Solidification: Based upon replots of Nelson's data, the following equations for initial transverse solidification have been derived: for the 13x13-in. ingot, $d = -0.50 + 1.2\sqrt{t}$; for the 17x17-in. ingot, $d = -0.10 + 1.04\sqrt{t}$. The parabolas of initial transverse solidification for these two ingots and that for the 32x32-in. ingot have been plotted in Fig. 12.[†] The plot indicates that the k value of

† As the negative constant in the Chipman-FonDersmith equation is believed to vary with superheat, the same constant, -0.10 , was used in all three equations from which the curves were plotted.

initial transverse solidification varies inversely with ingot width. The reason for this may be considered.

Fig. 12—Effect of ingot width on initial transverse solidification.

Temperature gradients established in mold walls from the middles of the hot sides to the less hot corners affect the k value for solidification across the middle plane. As ingot width decreases, the corner chills become increasingly effective. Thus k varies inversely with ingot width. As ingot width increases above some limiting width, perhaps 35 to 40 in., however, mold corners exert no further influence on heat extraction at the middle plane; that is, the normal k value for a given wall thickness is attained.

In addition to ingot width, mold-wall thickness influences k . Experimental data reported by Bishop, Brandt, and Pellini⁷ indicate that k increases with increase of mold-wall thickness from $1\frac{1}{2}$ to $4\frac{1}{8}$ in. Data reported by Nelson¹ indicate that k increases with increase of wall thickness from $4\frac{1}{4}$ to $6\frac{1}{4}$ in. It seems not improbable that k would increase with further increase of wall thickness up to the maximum thickness used for mold walls.

In mold design, wall thickness is commonly increased with increase of ingot width. Hence the effect of the latter upon k is somewhat moderated by the opposite effect of the former factor. As both influences are reflected in the plotted curves (Fig. 12), however, the k values for transverse solidification of ingots of widths intermediate between 13 and 32 in. may be determined approximately by interpolation between the curves for these two ingots.

Vertical Solidification: Nelson's data for vertical solidification in his 13x13 and 17x17-in. ingots have been replotted on the same chart (Fig. 13), on which has been reproduced also the curve for the

32x32-in. ingot, Fig. 11. As in the last curve, the last plotted point for each of Nelson's ingots lies well above the initial curve through the first three points. Accelerated vertical solidification in the 13x13-in. ingot has been represented as a straight line through the last two points, the slope of which line is the minimum consistent with the data. A pattern for vertical solidification curves clearly emerges. The slope of the line through the last observed point for the 17x17-in. ingot has been determined by interpolation between the final curves for the 13x13 and 32x32-in. ingots. Complete vertical solidification curves for 20x20, 25x25, and 30x30-in. ingots, shown as dashed lines, have been developed similarly by interpolation between the curves for the above two ingots. The slopes of the final portions of the curves are uncertain; they may decrease upwardly a variable amount depending on segregation in ingot interiors.

Fig. 13—Effect of ingot width on vertical solidification.

From Fig. 13, vertical solidification curves are apparently composed of two portions: an initial curve approximating a parabola and a final curve of steep slope. The two portions intersect at a height equal to approximately one-half the base width of ingot. The slopes of both portions decrease with increase of ingot width.

Accelerated Solidification in Ingots

As long as heat extraction is unidirectional, that is, all components are parallel, solidification follows the Chipman-FonDersmith equation, $d = -C + k\sqrt{t}$. When components of heat extraction occur in more than one direction, solidification, for the purposes of this paper, is said to be accelerated. Accordingly, solidification from curved surfaces and from ingot corners proceeds at accelerated rates from the start. The face of accelerated solidification widens as it proceeds inwardly in ingots to form zones of accelerated solidification. The zones originating at both side and base corners of ingots are considered below.

Accelerated Transverse Solidification from Side Corners: Nelson¹ noted that the faces of the cavities of 17x17-in. ingots dumped later than 20 min after pour were completely curved; that is, the faces of accelerated solidification arising at the corners had reached the middle planes. With a k value of 1.04 for the latter ingot, solidification would attain a

Fig. 14—Solidification curves for Homestead Works' 32x32 in. ingot.

depth of about $4\frac{1}{2}$ in., or approximately one-fourth the face width, in 20 min. This proportionality of depth to face width may be expected to apply approximately to all square and rectangular ingots. Plotted dumped ingot data^{1,10} (Fig. 10), however, fail to show any appreciable acceleration at such depths. It may be concluded, therefore, that acceleration of transverse solidification caused by components of heat extraction to adjacent sides is too slight to be noticeable at the middle planes of ingots of commercial sizes.^{††}

^{††} In small laboratory ingots, acceleration of this type may be quite significant.

Initial Accelerated Vertical Solidification: Analogous to the above, accelerated vertical solidification from base corners may be expected to reach the vertical axis at a height equal to about one-fourth the base width. Evidence that it does is found in the macroetch of Homestead Works' 29x66-in. ingot, Fig. 17. Above line *ada* vertical columnar crystals slope inwardly, which indicates that transverse components of heat extraction became effective along this line. The height, *d*, at which accelerated vertical solidification reaches the vertical axis is about 7 in., or about one-fourth the base width. Zone *adac* (Fig. 17), the upper portion of base cone *aca*, is therefore the zone of initial accelerated vertical solidification.

Vertical solidification from the rounded bases of big-end-up ingots occurs at accelerated rates from the start. If, for example, the data for the first four 32x32-in. ingots (Fig. 11) be plotted on a d/\sqrt{t} basis, the resulting curve increases in slope inwardly. Such a curvature denotes accelerated solidification (the plot of unaccelerated solidification on a d/\sqrt{t} basis is a straight line, Fig. 10).

Accelerated Transverse Solidification from Base Corners: Of much more practical importance than either of these two types of accelerated solidification is accelerated transverse solidification originating at base corners (*a* in Fig. 18) of big-end-down ingots, or at the points of tangency between the straight sides and the rounded bases of big-end-up ingots (*a* in Fig. 15). The loci of this acceleration, *ag* (Figs. 15 and 18), and its effects upon ingot soundness, will be discussed later.

Fig. 15—Solidification pattern of Homestead Works' 32x32-in. big-end-up ingot.

Final Accelerated Vertical Solidification: Analogous to base cone *aca* (Fig. 17), as outlined by crystal structure in Homestead Works' 29x66-in. ingot, so-called base cones of vertical solidification *aca* (Fig. 15) are developed in big-end-up ingots. The height of the base cone is about one-half the base width of an ingot, Figs. 15 and 17. As this is also the height at which sharp acceleration of vertical solidification occurs (Fig. 13), a clue is provided as to the cause of this acceleration. At the tip of the base cone, the faces of transverse solidification from opposite sides first meet at the vertical axis, Figs. 15 and 18. Hence transverse components of heat extraction are here added to the vertical components. The added transverse components appear to be responsible for the high rates of final accelerated vertical solidification.

It has been generally assumed that vertical solidification is confined to the base cones of ingots. In the following, it is hoped to show: 1—that vertical solidification extends above the base cone in most ingots, and 2—that its extent is the determinant of the axial soundness of ingots.

Solidification Pattern of Big-End-Up Ingot: To aid in the development of the solidification pattern of Homestead Works' 32x32-in. ingot, the curves of transverse (Fig. 10) and vertical (Fig. 11) solidification of this ingot have been placed on the same chart (Fig. 14) to the same time scale but to different dimensional scales. The vertical scales have been adjusted so that one-half the top width, 16 in., on the left-hand scale for transverse solidification equals the full height of the ingot, 72 in., on the right-hand scale for vertical solidification. The direction in which solidification is completed, then, is determined according to which curve first attains the top horizontal line denoting completion of solidification in either direction. The curve of vertical solidification, OCV, reaches 72-in. height at V at about 187 min after pour; the curve of transverse solidification, OT, would not reach the same hori-

zontal line, representing 16-in. depth, until much later; that is, solidification of this ingot was completed vertically rather than transversely.

Accelerated Transverse Solidification: Fig. 14 also shows curves of accelerated transverse solidification, plotted from data obtained from the dumped ingots, Figs. 6 to 8. For example, points *b*₃ and *b*₄ represent the wall thicknesses at 26-in. height as measured in ingots Nos. 3 and 4, Fig. 7. A straight line through these points intercepts parabola OT at point *b*; that is, accelerated solidification at 26-in. height began at about 7-in. depth and 66 min after pour.

Similarly, points *e*₅ and *e*₆ in Fig. 14 represent wall thicknesses as measured at 56-in. height in ingots Nos. 5 and 6, Fig. 8. Line *e*₅*e*₆ through these points is approximately parallel to line *b*₃*b*₄, and intersects parabola OT at *e*. Points *b* and *e* have been plotted on the solidification pattern of the 32x32-in. ingot in Fig. 15. Points *b* and *e*, plotted similarly on the split ingots, Figs. 7 and 8, lie on or in line with inner lines of inverted-V segregation, Fig. 1. These coincidences suggest that inner lines of inverted-V segregation are loci of acceleration of transverse solidification from base corners. Additional evidence to this effect is provided by Homestead Works' 29x66-in. ingot. Inner lines *ag* in the sulphur print, Fig. 16, have been reproduced as dashed lines *ag* in the macroetch, Fig. 17. The increased width of columnar crystals beyond these lines and their increased upward slope, particularly in the lower portion of the ingot, are indicative of added vertical components of heat extraction.

In addition to the evidence given, there appears to be a logical reason for the coincidence of inner lines of inverted-V segregation and acceleration of transverse solidification. As solidification rates decrease inwardly, the layer of liquid segregated metal adjacent to the face of solidification increases in concentration.^{2,5} Conversely, when solidification rates accelerate, the concentration of this segregated layer must decrease. The excess segregation above that which can be carried at the higher rates is, therefore, deposited where the rates increase.

In further support of the coincidence of inner lines of inverted-V segregation and acceleration of transverse solidification, inner lines invariably point to the base corners of big-end-down ingots (Figs. 3, 4, and 24 to 26), whence accelerated solidification proceeds.

In view of the above evidence, inner lines of inverted-V segregation have been utilized as loci of accelerated transverse solidification in the construction of the solidification pattern of the 32x32-in. ingot. Thus the depths of the inner line of inverted-V segregation, as measured to points *d*, *f*, and *g* in Fig. 8b at 48, 66, and 72-in. heights, respectively, on the right-hand side of ingot No. 6, have been plotted on both parabola OT in Fig. 14 and the solidification pattern in Fig. 15. The depths of solidification to points *d'*, *f*₆, and *g*₆ at the above heights in ingot No. 6 in Fig. 8b have also been plotted on both the solidification chart and pattern. Through these points have been constructed lines *dd'*, *ff*₆, and *gg*₆, representing accelerated solidification at the above heights, Fig. 14. These lines are approximately parallel with lines *bb*₄ and *ee*₆, previously developed. Accelerated solidification is thus revealed as progressing upwardly in the ingot from the base to the top, its rates not varying greatly. Lines *ag*, Fig. 15, constructed through points *b*, *d*, *e*, *f*, and *g*, then, are loci of acceleration of transverse solidification.

Fig. 16—Sulphur print of 29x66 in. ingot, semikilled steel. Ladle analysis: C, 0.24 pct; Mn, 0.44; P, 0.013; S, 0.033; Si, 0.032. Ingot split at Homestead Works.

In further support of their coincidence, lines ag , Fig. 15, correspond closely with the inner lines of inverted-V segregation faintly visible on the left-hand side of the 32x32-in. ingot, Fig. 9.

The Vertical Core: The vertical core of an ingot in a solidification pattern is outlined by the points of tangency between the faces of vertical and transverse solidification, such as point d' at 48-in. height in ingot No. 6, Fig. 8b. At the time that transverse solidification is completed at d' at 48-in. height, however, vertical solidification has reached a height of only about 45 in. on the vertical axis. Similarly, transverse solidification would be completed at 26-in. height when vertical solidification had reached point i in Fig. 14 at 23-in. height on curve CV of vertical solidification. Accordingly, point b' has been located on extrapolated line bb , vertically above point i . Points b' and d' have been plotted at their proper depths on both sides of the solidification pattern in Fig. 15. As the width of the vertical core apparently decreases upwardly, so does the differential between the heights of vertical and completed transverse solidification. For this reason, point g' has been located on extrapolated line gg , Fig. 14, vertically below point j at 70-in. height on curve CV of vertical solidification. Points g' have also been plotted on the solidification pattern in Fig. 15. As the vertical core of an ingot lies directly above the base cone, Fig. 17, the vertical core in the 32x32-in. ingot has been constructed from the tip of the base cone c (Fig. 15) through points b , d , and g .

The width of V segregation faintly visible in the upper portion of the split full 32x32-in. ingot, Fig. 9, is approximately equal to the width of the vertical

Fig. 17—Macroetch of 29x66 in. ingot, semikilled steel. Ladle analysis: C, 0.24 pct; Mn, 0.41; P, 0.017; S, 0.036; Si, 0.048. Ingot split at Homestead Works.

core in the corresponding location in the solidification pattern, Fig. 15. This indicates that V segregation is developed in vertical solidification in the vertical cores of ingots.

Isochrones: Isochrones at 20-min intervals have been constructed in the outer zone of the ingot in Fig. 15 parallel to its sides at depths as determined from parabola OT in Fig. 14. Curved-line isochrones, spaced on the vertical axis according to the curve of vertical solidification, Fig. 11, have been constructed in the base cone and in the vertical core. The isochrones have been connected by straight lines across the zones of accelerated transverse solidification. Dashed lines g_h correspond in location

Fig. 18—Solidification pattern of Homestead Works' 29x66 in. big-end-down ingot.

to the actual face of solidification, $g_h c_s$ (Fig. 8b), on the right-hand side of ingot No. 6.

Discussion: With only two points for their establishment, the curves of accelerated transverse solidification, Fig. 14, have been constructed as straight lines. As the spacing of isochrones in the zone of accelerated transverse solidification, Fig. 15, is so nearly uniform, probably little error is involved in this representation.

It is of interest to reconstruct the face of solidification in ingot No. 5, Fig. 8a, from data obtainable from the solidification chart, Fig. 14. As the reconstructed outline $e_h h_s e_s$ closely bounds the porous zone, it appears probable that this would be the normal face of solidification.

Solidification Pattern of Big-End-Down Ingots

Although not of the same ingot, the sulphur print (Fig. 16) and macroetch (Fig. 17) of 29x66-in. big-end-down ingots split at Homestead Works appear

Fig. 19—Solidification curves for Nelson's 13x13 in. ingot.

to match each other closely. The ingots were cast in molds of 9.6-in. mean wall-thickness, having $\frac{3}{4}$ -in. corrugations.

The base cone aca and the vertical core $g'cg'$, Fig. 17, of equiaxed crystals are clearly distinguishable by macrostructure. These zones have been outlined on the solidification pattern in Fig. 18. The width of the vertical core, as indicated by two pairs of short lines in the upper portion of the sulphur print, Fig. 16, is about equal to the width of V segregation just above them. This confirms the evidence from the 32x32-in. ingots that V segregation develops in vertical cores of ingots.

Above line ada in Fig. 17 vertical columnar crystals slope inwardly, which indicates that transverse components of heat extraction were effective. Zone $adac$ in Figs. 17 and 18 is the zone of initial accelerated vertical solidification. As discussed previously, lines ag in Figs. 17 and 18, located similarly to inner lines of inverted-V segregation in the sulphur print in Fig. 16, coincide with crystal structure changes, which changes indicate that solidification beyond these lines occurred at accelerated rates. Hence zones $gacg'$ in Fig. 18 are zones of accelerated transverse solidification.

Based upon rates of transverse and vertical solidification estimated from the curves in Figs. 12 and 13, respectively, isochrones at 20-min intervals have been constructed in the solidification pattern in Fig. 18.

The solidification pattern of the big-end-down ingot, Fig. 18, and that of the big-end-up ingot, Fig. 15, are similar in that both have a vertical core which extends from the tip of the base cone to the top of the ingot. These vertical cores surmount zones of accelerated vertical solidification and are surrounded by zones of accelerated transverse solidification.

Proposed Mechanisms for Segregation in Ingots

Based on the developed solidification patterns of Figs. 15 and 18 and supporting data, the following mechanisms for the several types of segregation in ingots are proposed:

V Segregation: V segregation in ingots appears to result from the entrapment of segregated liquid metal adjacent to the face of vertical solidification by the earlier solidification at higher temperatures of purer metal above the segregated layers. Originally hemispherical, entrapped layers become distorted during cooling, so that they approximate a V shape in ingot sections, Figs. 1, 2, and 3.

In small ingots and in some large ingots of unusual proportions, solidification may be completed transversely rather than vertically. As will be discussed later, the axial characteristics of such ingots differ from those of ingots that develop vertical cores.

Zone of Negative Segregation: Because segregation may ascend readily from the broad face of vertical solidification in the lower portion of an ingot (Figs. 15 and 18), the liquid metal here is relatively pure. Because metal of the highest purity selectively solidifies first,² metal of less than average concentration of segregating elements solidifies in the lower middle portions of ingots. As solidification advances upwardly, the concentration of segregation in the liquid and consequently in the solid metal progressively increases, Fig. 1.

Inner Lines of Inverted-V Segregation: The concentration of segregation in the layer of liquid metal

adjacent to the face of transverse solidification increases as solidification rates decrease inwardly. Conversely, when these rates increase, the concentration of segregation must decrease. Thus the excess segregation above that which can be carried at the higher rates is entrapped along the loci of acceleration.

Outer Lines of Inverted-V Segregation: Although outer lines of inverted-V segregation may originate at various heights in an ingot (Fig. 1), all start at approximately the same depth. The beginnings of outer lines of inverted-V segregation have been indicated by the letter *x* in Homestead Works' 32x32-in. ingots No. 2 (Fig. 6b), 3 and 4 (Fig. 7). According to the theory of selective solidification, there would have been a continuous layer of segregated liquid metal adjacent to the face of solidification in ingot No. 1, Fig. 6a. The presence of termini, *x*, of segregated layers in ingots Nos. 2, 3, and 4, indicates, therefore, that the originally continuous segregated layer was penetrated at random locations by columnar dendrites. Segregation could rise readily from the upper side, but not from the lower side of a penetrating dendrite. As a segregated layer is slightly insulating,³ the upper side of the dendrite would then offer a preferred course for heat flow. Hence solidification could advance upwardly beyond the segregated layer and entrap this layer. As solidification progresses upwardly beyond segregated layers, however, transverse solidification continues inwardly. Hence outer lines of inverted-V segregation slope inwardly in an upward direction.

Fragmentary lines of inverted-V segregation, as designated by letters *y-y* in Fig. 16, sometimes occur inside the prevailing inner lines, *ag*, of inverted-V segregation, that is, in the zones of accelerated transverse solidification. These segregated layers may be entrapped by a mechanism analogous to that described for the entrapment of outer layers of inverted-V segregation. The increased angles of these lines with the vertical, as compared with those of the prevailing inner lines, *ag* in Fig. 16, attest to the higher rates of transverse relative to vertical solidification in zones of accelerated transverse solidification as compared with those in outer zones.

Effect of Ingot Design on Solidification Pattern

As the ultimate objective of ingot solidification studies is to improve ingot soundness and uniformity, it seems important to consider the practical aspects of both ingot and mold design.

In the same manner that the curves of transverse and vertical solidification for Homestead Works' 32x32-in. ingot have been plotted on the same chart, Fig. 14, the curves for Nelson's 13x13 and 17x17-in. ingots, respectively, have been plotted together, Figs. 19 and 20. In these two charts also, the vertical scales have been adjusted so that one-half the top width of the ingot on the left-hand scale for transverse solidification equals the full height of the ingot on the right-hand-scale for vertical solidification. The direction in which solidification is completed, then, is determined according to which curve first attains the horizontal line denoting completion of solidification in either direction. As discussed previously, solidification would be completed vertically in the 32x32-in. ingot, Fig. 14. In the 13x13-in. ingot, on the other hand, solidification would be completed transversely, Fig. 19. At the time of this completion, vertical solidification would have attained a relatively short height of only about 22 in.

Fig. 20—Solidification curves for Nelson's 17x17 in. ingot.

In the 17x17-in. ingot, Fig. 20, vertical solidification would have reached a height of about 44 in. at completion of transverse solidification across the top. Hence, in an ingot somewhat shorter than the 17x17-in. ingot, or in one of slightly greater top width, transverse and vertical solidification would be completed to the top middle of the ingot at the same time.

Based upon these three charts, then, it appears that three types of solidification pattern may occur in ingots, Fig. 21. An ingot in which transverse and vertical solidification reach the top middle simultaneously, Fig. 21b, may be termed an ingot of critical *w/h* ratio. In an ingot of lower than critical *w/h* ratio, Fig. 21a, vertical solidification does not reach the top of the ingot. The height, *v*, of the vertical core in ingots of this type decreases with decrease of the *w/h* ratio. In ingots of greater than critical *w/h* ratio, Fig. 21c, the width, *V_c*, of the vertical core at the top increases with increase of *w/h* ratio.

Fig. 21—Typical solidification patterns of ingots of different *w/h* ratios.

b (right) — Ingot cast in sand mold. Bessemer steel. Ladle analysis: C, 0.48 pct; Mn, 0.82; P, 0.028; S, 0.041; Si, 0.27. Ingot dimensions: 11.9 in. square at top, 10.2 in. square at base, 3 ft 9 in. long.

Fig. 23 (below and right)—Sulphur prints of 26 in. diam ingots of low w/h ratio cast big-end-up and big-end-down in same mold. Ingots split at Homestead Works.

a (below)—Big-end-up. Height of ingot, 164 in. Ladle analysis: C, 0.32 pct; Mn, 0.72; P, 0.035; S, 0.035; Si, 0.26; Ni, 3.37.

b (right)—Big-end-down. Height of ingot, 187 in. Ladle analysis: C, 0.32 pct; Mn, 0.90; P, 0.016; S, 0.022; Si, 0.22; Ni, 2.90.

The top width of an ingot of critical w/h ratio may be termed the critical width for an ingot of given height. The critical width of an ingot will vary with both height and type (big-end-up or big-end-down). From calculations based upon the curves of transverse (Fig. 12) and of vertical (Fig. 13) solidification, the critical width of a big-end-up ingot of 65-in. height is estimated to be about 18 in.; the critical width of a big-end-down ingot of the same height would be somewhat greater, perhaps about 21 in.

The type of solidification pattern, as governed by the w/h ratio, has an important effect on the type and extent of axial defects in ingots. Examples of ingots of all three types are discussed in the following.

Ingots of Low w/h Ratios: Ingots of low w/h ratios are usually comparatively small (say, from 9 to 15 in. sq). Because of their relatively rapid rates of solidification, small ingots develop relatively little segregation. For special applications, however, ingots of much larger sectional areas may be abnormally long, hence have a low w/h ratio.

In Fig. 22a is the sulphur print of a small ingot of low w/h ratio, reproduced from the First Report on the Heterogeneity of Steel Ingots of the British Iron and Steel Institute.² The axial characteristics of this ingot are different from those of ingots of higher w/h ratios, Figs. 2 and 3. In the small ingot, the V zone is widest at the top and tapers downwardly to disappearance at about 25 pct above the base. The V-shaped defects are of approximately uniform intensity throughout their extent. The shape of the V zone indicates that the faces of transverse solidification remained parallel to the sides as they advanced inwardly; that is, solidification was completed transversely to the middle of the ingot. Vertical solidification, then, must have been confined to the lower 25 pct of the ingot.

In ingots that complete solidification transversely, the so-called V segregation probably develops according to Hultgren's mechanism⁴ described previously; that is, layers of liquid metal are entrapped interdendritically as the faces of solidification from opposite sides meet at the vertical axis. Regardless of the amount of segregation present, porosity develops upon solidification of entrapped liquid metal. For this reason, it appears that V porosity is a more accurate term than V segregation as applied to axial defects in ingots of low w/h ratios.

That V porosity develops also in large ingots of low w/h ratios is apparent from the sulphur print of the 26-in. diam big-end-up ingot split at Homestead Works, Fig. 23a. The large big-end-down ingot of low w/h ratio, Fig. 23b, was cast in the same mold, inverted, as was the big-end-up ingot, Fig. 23a. Because solidification was completed across the top transversely before it was across the lower portion of this ingot, a central cavity developed. Similar cavities will necessarily develop in all big-end-down ingots of low w/h ratio. For big-end-down ingots to be solid, therefore, they must be of high w/h ratio, that is, they must have a vertical core extending to the top of the ingot, Fig. 17.

The wide V's in the ingot of low w/h ratio cast in a sand mold, Fig. 22b, are indicative of a wide core of vertical solidification. Abnormally slow rates of transverse solidification, caused by casting in a sand mold, appear to be responsible for both the abnormally wide vertical core and the abnormally shallow depths of the lines of inverted-V segregation.

Fig. 24—Sulphur print of 10½ ton big-end-down ingot, electric furnace steel. Ladle analysis: C, 0.30 pct; Mn, 0.74; P, 0.010; S, 0.017; Si, 0.13. Reproduced from first "Report on the Heterogeneity of Steel Ingots," Iron and Steel Institute, London (1926).

Ingots of Near-Critical w/h Ratios: Ingots of near-critical w/h ratios comprise generally those of intermediate sizes, say, from 15 to 25-in. widths. The solidification rates of these ingots are sufficiently slow for a sufficiently long time that appreciable segregation may develop. Since the vertical cores of such ingots are typically narrow (Fig. 21b), segregation may not ascend readily into the sinkhead. For these reasons, V segregation is more prevalent in ingots of near-critical w/h ratios than in ingots of either higher or lower ratios. Big-end-up design effects substantial improvement in the internal soundness of ingots of near-critical w/h ratios, Figs. 2 and 3.

Ingots of High w/h Ratios: Ingots of this type comprise so-called large ingots of over 25-in. width. As the width, V , in Fig. 21c, of the vertical core at the top increases with increase of the w/h ratio above the critical ratio, ascent of segregates from the liquid metal in the ingot body to the sinkhead is facilitated. Thus, even though large ingots normally develop more segregation than do small ingots, the former, Figs. 4 and 9, may be fully as sound as the latter, Fig. 2.

The width of the vertical core is related to the width of the bottleneck or narrowest space between inner lines of inverted-V segregation in ingots, $g-g$

Fig. 25 (above)—Sulphur print of large big-end-down ingot. No data supplied. Reproduced from first "Report on the Heterogeneity of Steel Ingots," Iron and Steel Institute, London (1926).

Fig. 26 (right)—Macroetch of 55 in. diam big-end-up ingot. Ladle analysis: C, 0.37 pct; Mn, 0.57; P, 0.018; S, 0.028; Si, 0.19. Ingot split at Homestead Works.

in Figs. 15 and 18. Large ingots, big-end-up as well as big-end-down, in which the bottleneck is too narrow, are subject to excessive V segregation, Fig. 25, and/or secondary pipe, Fig. 26. Large ingots, big-end-down as well as big-end-up, with bottlenecks of adequate width, are typically sound, Figs. 4, 9, and 24.

Mold Design

As discussed above, ascent of segregates into the sinkhead is facilitated by a wide column of liquid metal in the upper portion of an ingot in the final stages of solidification, Figs. 15 and 18. The width of this column is reflected in both the width of the vertical core and that of the bottleneck between inner lines of inverted-V segregation. Differences in these widths constitute the most significant differences between the solidification patterns of big-end-up, Fig. 15, and big-end-down, Fig. 18, ingots. They are reflected in differences in axial soundness between ingots of the two types, Figs. 2 and 3.

Width V_v , Fig. 21c, of the vertical core at the top of an ingot, which may be measured as the width of V segregation, is a convenient single criterion of

internal quality. Increased width V_v favors improved ingot soundness. Width V_v is principally dependent upon two factors: 1—the w/h ratio, already discussed, and 2—the relative rates of transverse solidification across the top, and of vertical solidification. Decrease of the former and increase of the latter rates, relative to each other, favor increased width V_v . The relative rates in the two directions may be influenced by the following features of mold design: 1—type of mold, whether big-end-up or big-end-down, 2—mold-wall thickness, and 3—mold-wall taper. The effects of each factor are considered below.

Type of Mold: The advantage of big-end-up design arises principally from the fact that the ingot tops are wider than those of big-end-down ingots; that is, the former ingots have normally higher w/h ratios than the latter. But the narrower, rounded bases of big-end-up ingots favor earlier and more rapid rates of final accelerated vertical

solidification in the vertical cores of these ingots as compared with big-end-down ingots, Figs. 15 and 18. The closed bases of big-end-up molds probably also increase the effectiveness of mold walls in extracting heat. Because their molds are closed-based, big-end-up ingots are sometimes advantageously shorter than big-end-down ingots of similar cross section.

Mold-Wall Thickness: Mold-wall thickness affects the rates of vertical as well as those of transverse solidification. The optimum wall thickness is one that will result in a minimum ratio between rates of transverse and of vertical solidification.

In experiments conducted at Duquesne Works, 25x25-in. ingots cast in molds of 3-in. uniform wall-thickness had narrower V's and more center segregation than did ingots of the same size cast in molds of standard 5½ in. mean wall-thickness. Apparently the thin wall reduced the rates of vertical solidification relatively more than it did those of transverse solidification. There is evidence, on the other hand, that excessively thick mold walls may increase rates of transverse solidification relatively more than they increase rates of vertical solidification. For example, the mean wall-thickness of the mold in which the 55-in. diam ingot, Fig. 27, was cast was 15⅜ in. The unsound center in the upper portion of this ingot may have been caused by too rapid rates of transverse solidification.

The service life of a mold appears to be related to its wall thickness.¹⁴ Based on studies of extensive data, Bacon¹⁴ finds an optimum M/I ratio (mold weight/ingot weight) of 0.88 for molds of over 6-ton weight. This ratio would result in a 10-in. wall thickness for the above mold.

In summary, for an ingot of any given size there is probably an optimum mold-wall thickness to result in a minimum ratio between rates of transverse and vertical solidification. From superficial scrutiny, it appears probable that optimum mold-wall thicknesses for quality do not vary greatly from those for maximum mold life.

Mold-Wall Taper: Apparently to facilitate solidification from the base upwardly in ingots, mold walls are commonly made 1 to 4 in. thicker at the base than at the top. But dumped ingot data,¹ Fig. 6a, indicate that, except for accelerated solidification, rates of transverse solidification are uniform throughout the height of ingots cast in molds with tapered walls. The reason that mold-wall taper is ineffective for the purpose intended appears to be that heat flows downwardly in mold walls from the thin, hot, top portions to the thick, less hot, base portions. As a result, the normally slower rates of heat extraction by the thin top portions are increased, the normally faster rates of heat extraction by the thick base portions are decreased, and solidification rates are equalized throughout the height of the ingot. Thus, although thick base portions may advantageously increase final rates of accelerated vertical solidification, mold-wall taper appears to be of limited value in improving ingot solidification patterns.

Alloy Steels

The foregoing discussions apply to molds used in casting carbon steels or steels which solidify similarly to carbon steels. Certain low-alloy steels, cast in molds which produce sound carbon-steel ingots, develop exaggerated axial porosity, Fig. 27. Sykes¹⁸ reports "central looseness" in ingots of an austenitic high alloy steel, R. ex 78. Low-alloy steels have

Fig. 27—Macroetch of 22x22 in. ingot, AISI 4340 steel. Ladle analysis: C, 0.40 pct; Mn, 0.68; P, 0.012; S, 0.014; Si, 0.28; Ni, 1.78; Cr, 0.70; Mo, 0.24. Ingot split at Duquesne Works.

strong tendencies toward equiaxed crystals, and austenitic steels toward columnar crystals. Ingots of both types, however, were solid just below the hot-top junction, Fig. 27; that is, solidification was completed transversely across the top before the vertical core was completely solid. Thus the critical w/h ratios, Fig. 21b, for these alloy-steel ingots must be considerably higher than that for carbon-steel ingots.

Sykes determined that exaggerated taper in big-end-up ingots was ineffective in preventing axial porosity. But ingots of R. ex 78 steel cast in sand had completely sound interiors. As shown by the ingot in Fig. 22b, this method of casting results in a wide vertical core. Unfortunately, however, these slow-cooling ingots had excessively large crystals and cracked badly in rolling.

For alloy-steel ingots to be completely sound, it

would be necessary for them to have a higher w/h ratio; that is, to be broader and/or shorter than carbon-steel ingots. From practical considerations, however, the extent to which the w/h ratio may be increased is limited.

Future Trends in Mold Design

As it seems doubtful that w/h ratios of ingots may be increased appreciably above those now used, improved ingot soundness appears to rest upon improved mold design. The benefits to be gained by adjustment of the several factors in molds of conventional design appear to be limited. Although some improvement may be attained by developing the optimum thickness for mold walls, particularly for large molds, there seems to be little prospect for marked gains by adjustment of either ingot or mold-wall taper.

Because of the inherent limitations of molds of conventional design, it seems that departures from conventional mold design should be considered. These should be aimed at increasing rates of vertical solidification and decreasing rates of transverse solidification across the top of an ingot, relative to each other, to the maximum extent practicable. Heat flow in mold walls, which does not appear to have been given adequate attention, needs to be considered.

From viewpoints of both quality and economy, the walls of many large molds in current-use appear to be too thick. Further, as large ingots complete solidification vertically rather than transversely, the purpose of excessively thick walls—to reduce the time for complete solidification—is not accomplished. As the advantage of big-end-up over big-end-down casting decreases with increase of ingot size, large ingots may more advantageously be cast in big-end-down molds of moderate wall-thicknesses.

Conclusions

The following conclusions concerning ingot solidification and hypotheses regarding segregation in ingots appear to be consistent with all of the data examined.

In solidifying, ingots develop a core of vertical solidification above the base cone. The vertical core surmounts a zone of accelerated vertical solidification and is surrounded by zones of accelerated transverse solidification.

In ingots of low width/height (w/h) ratio, the vertical core does not reach the top. Above the vertical core, solidification is completed transversely and V porosity may be developed axially.

In ingots of intermediate w/h ratios (15 to 25-in. widths), the vertical core at the top is narrow. Such ingots are subject to excessive V segregation. Big-end-up casting is most advantageously applied to ingots of these ratios.

The width, V_v , of the vertical core at the top of an ingot increases with increase of w/h ratio above the critical ratio. Sound interiors depend upon development of a vertical core of adequate width V_v .

V segregation is formed in the vertical cores of ingots as a result of entrapment of the layer of segregated liquid metal adjacent to the face of vertical solidification by the prior solidification of purer metal above this layer.

The zone of negative segregation in the lower middle portions of ingots develops as a result of selective solidification vertically of the purest metal available from the relatively pure metal in the lower portion of the contained liquid metal.

Inner layers or lines of inverted-V segregation result from the entrapment of excess segregation above that which can be carried forward at accelerated rates of transverse solidification. Outer layers or lines of inverted-V segregation result from penetration of the segregated layer of liquid metal adjacent to the face of solidification by columnar dendrites. Following such penetration, solidification may progress inwardly and upwardly, and entrap the segregated layer.

Little improvement in internal quality of ingots may be anticipated from increase of ingot taper or mold-wall taper beyond those now used in molds of current design.

There appears to be an optimum mold-wall thickness for each ingot size to result in maximum width of vertical core, V_v , at the top of an ingot. The walls of some molds of current design, particularly those for large ingots, appear to be too heavy from both quality and economy viewpoints.

Departures from current mold design should be considered. These should be aimed at increasing rates of vertical relative to those of transverse solidification in ingots.

Acknowledgments

The interest and cooperation of staff members of the Metallurgical Dept., Homestead Works, in these ingot solidification studies, particularly their permission to use the photographs of the split dumped 32x32-in. ingots and other ingots, is acknowledged. It is desired also to express appreciation of the considerable amount of experimental work performed by the Metallurgical Dept., Duquesne Works, some of which has been mentioned. Thanks are extended to the several members of the staff of the Research and Development Division for their constructive suggestions and criticism in the preparation of this paper.

Aluminum-Oxygen Equilibrium in Liquid Iron

by Nev A. Gokcen and John Chipman

Aluminum and oxygen dissolved in liquid iron were brought into equilibrium with pure alumina crucibles and atmospheres of known H_2O and H_2 contents to study the reactions: $1-\text{Al}_2\text{O}_3(\text{s}) = 2 \text{ Al} + 3 \text{ O}$; $2-\text{Al}_2\text{O}_3(\text{s}) + 3\text{H}_2(\text{g}) = 2 \text{ Al} + 3\text{H}_2\text{O}(\text{g})$; and $3-\text{H}_2(\text{g}) + \text{O} = \text{H}_2\text{O}(\text{g})$. Aluminum strongly reduces the activity coefficient of oxygen and similarly oxygen reduces that of aluminum. Values of the product $[\% \text{ Al}]^2 \cdot [\% \text{ O}]^3$ are much smaller than those found in previous experimental studies and are of the order of magnitude of the calculated values.

ALUMINUM is the strongest deoxidizer commonly used in steelmaking, but the extent to which it removes dissolved oxygen has been debatable. The relationship between aluminum and oxygen has not been determined reliably not only on account of the usual experimental difficulties at high temperatures but also because of uncertainties in the analyses of very small concentrations of oxygen and aluminum.

The earliest experimental attempt of Herty and coworkers¹ was followed by a more systematic study of Wentrup and Hieber.² These authors added aluminum to liquid iron of high oxygen content in an induction furnace and considered that 10 min was sufficient to remove the deoxidation products from the melt. Parts of the melts thus obtained were poured into a copper mold and analyzed for total aluminum and oxygen (soluble plus insoluble forms), assuming that the insoluble parts were in solution at the temperatures from which samples were taken. It is conceivable that the furnace atmosphere in their experiments, consisting of mainly air at 20 mm Hg pressure, was a serious source of continuous oxidation and therefore that their oxygen concentrations were correspondingly high. Scattering of their data was explained to be well within the maximum inaccuracy of 10°C in the temperature measurements and errors of ± 0.002 pct each in the oxygen and total aluminum analyses. Maximum and minimum deoxidation values, i.e., values of the product $[\% \text{ Al}]^2 \cdot [\% \text{ O}]^3$ differed by factors of 10 to 15; mean values of 9×10^{-11} and 7.5×10^{-9} were reported at 1600° and 1700°C , respectively.

Hilty and Crafts³ determined the solubility of oxygen in liquid iron containing aluminum, using a rotating induction furnace. Pure alumina crucibles used in their experiments contained the liquid iron which in turn acted as a container for slags of varying compositions consisting mainly of Al_2O_3 , Fe_2O_3 , and FeO . The furnace was continuously flushed with argon, and additions of aluminum and Fe_2O_3 were

made in the course of each experimental heat. The inner surfaces of their alumina crucibles were covered with a substance other than pure Al_2O_3 , containing both iron oxide and alumina. Although frequent slag additions can change the composition of slag in the liquid iron cup formed by rotation, the inner surface of the crucible must depend upon the transfer of oxygen or aluminum through the liquid iron for any adjustment in composition. It is not clear that their metal was in equilibrium with the crucible wall, but it is clear that it was not in equilibrium with Al_2O_3 . Their deoxidation product, $[\% \text{ Al}]^2 \cdot [\% \text{ O}]^3$, varied by a factor of more than 50; the average values of 2.8×10^{-9} and 1.0×10^{-7} were selected for temperatures of 1600° and 1700°C , respectively.

Aside from the experimental determinations, attempts have been made to calculate the deoxidation constant for aluminum indirectly from thermodynamic data. Schenck⁴ combined the thermodynamic data for Al_2O_3 and dissolved oxygen in liquid iron by assuming an ideal solution. His calculated values are 2.0×10^{-15} and 3.2×10^{-13} at 1600° and 1700°C , respectively. Later, Chipman⁵ attempted to correct for the deviation from ideality and derived an expression which led to deoxidation values of 2.0×10^{-14} and 1.1×10^{-12} at 1600° and 1700°C , respectively. The errors in these treatments originate mainly from inaccuracies of thermal data and uncertainties regarding the activity coefficients of dissolved oxygen and aluminum.

The purpose of this investigation was to study the equilibria represented in the following reactions in the presence of pure alumina:

The experimental method consisted of melting pure electrolytic iron, usually with an initial charge of aluminum, in pure dense alumina crucibles under a controlled atmosphere of H_2O and H_2 and holding

* Heats 204 and 205 were made at 1680°C and $H_2O/H_2 = 5.12 \times 10^{-3}$. Others were made at 1723°C and $H_2O/H_2 = 3.72 \times 10^{-3}$.

it at a constant temperature until equilibrium was established between gas, liquid, and solid phases. The resulting melts of very small weight were quenched to retain the equilibrium concentrations of aluminum and oxygen and subsequently analyzed for these elements. The apparatus and procedure followed herein were described earlier in detail.⁶

In order to obtain concentrations of aluminum and oxygen high enough for analysis, it was planned to operate at temperatures higher than those used in previous studies.

Experimental Procedure

The procedure employed in these experiments was quite similar to that employed in the previous investigation.⁶ The main differences were as follows:

Slightly lower preheater temperatures were used in order to conserve the heating coil inside preheater. This was necessitated by the relatively dry hydrogen employed which had a strong tendency to embrittle the Pt-Rh alloy.

Experiments were conducted at considerably higher temperatures in order to obtain sufficient amounts of aluminum and oxygen for dependable analysis. At the usual experimental temperature of 1600°C, either the aluminum or the oxygen was always too low for accurate determination.

The temperature control and the accuracy of its measurement were within $\pm 10^\circ\text{C}$ even at the highest temperature used, 1866°C.

Known mixtures of H_2O and H_2 were obtained by passing purified hydrogen through the saturated solution of lithium chloride at various controlled temperatures. The vapor pressure of this solution had been determined previously in the same apparatus.⁷ The saturated hydrogen was mixed with four times its volume of purified argon.

Alumina crucibles used in this work were of the highest purity with less than 2 pct porosity. They were 1 in. high and 1 in. OD with a wall thickness of 0.04 in.

Operation: The charge consisted of 32 g of electrolytic iron containing a small percentage of aluminum in the form of pure Fe-Al alloy. The crucible was inserted in the furnace to the point where the surface of metal was 0.2 in. below the preheater. The preheater was brought to the desired temperature and the furnace flushed for a minimum period of 2 hr. Then the induction unit was turned on and the charge was brought to the desired temperature of 1700°C or more in less than 80 sec in order to preserve the aluminum in the charge. If the charge contained aluminum far beyond the equilibrium concentration, a thin and persistent scum of Al_2O_3 was formed on its surface a short time after reaching the desired temperature. Such heats were rejected, and a very thin grayish white solid scum was observed

on the quenched melts. In the satisfactorily charged heats the surface of melt was uniform and clean, permitting accurate temperature measurements with an optical pyrometer. After the attainment of equilibrium, the melts were quenched with hydrogen as described in the following section. Quenched equilibrium melts were shiny on the top and loosely attached to the alumina crucibles. Crucibles were only slightly discolored at 1866°C and were white at lower temperatures.

Quenching: The crucible was lowered into a position between two groups of orifices through which jets of hydrogen were directed upon it. Dense and very thin alumina crucibles without any radiation shields were used to facilitate the quenching process. It was found that by lowering the crucible into the cold zone of the silica furnace tube without the hydrogen jet the melt required a period of 60 sec to freeze, whereas in hydrogen quenching 7 to 12 sec was sufficient depending upon the temperature of melts.

Occasionally melts were spilled on the brass bottom when the crucibles cracked due to severe thermal shocks, thereby yielding severely quenched sound samples.

Oxygen Analysis: Oxygen analyses were made by the vacuum-fusion technique in the usual manner. The following precautions were taken to minimize the errors in the analytical results: Larger samples of 5 to 8 g were used. Very low and consistent blanks were obtained before proceeding with the analysis. This was accomplished by a long period of degassing of the vacuum-fusion apparatus. The aluminum content of the melt in the vacuum-fusion crucible was kept below 0.03 pct. Independent analyses were made by N. A. Gokcen to check the accuracy in the results.

The reproducibility of the oxygen analyses was generally within ± 0.0005 pct O.

Aluminum Analysis: Determination of aluminum was made by the gravimetric method⁸ in the range of 0.010 to 0.06 pct Al. The colorimetric method of analysis using aluminon as the indicator was used throughout the range investigated, yielding the soluble and insoluble aluminum separately. The agreement between the two methods was usually less than 0.001 pct in aluminum. The insoluble aluminum was approximately constant at each temperature, the average values being 0.0025, 0.0030, and 0.0055 at 1695°, 1760°, and 1866°C, respectively. In the absence of insoluble analyses for a very few heats, the average at each temperature level was added to the soluble aluminum content to obtain the total concentration. Average deviation in the duplicate analyses of total aluminum was always below ± 0.001 pct Al and usually of the order of ± 0.0006 pct.

Experimental Results

Attainment of Equilibrium: The experimental heats in Table I were made in order to ascertain the approximate time required for the establishment of equilibrium between three phases: gas, liquid metal, and solid alumina. Heats 204 and 205 were made at 1680°C under identical atmospheres without any aluminum in the charge. Analysis indicated that most of the aluminum was picked up from the crucible in about 6 hr, but there is no certainty that equilibrium was reached in 10 hr. Heat 208, with no aluminum in the charge, reached a slightly higher concentration than the next three in which the charge was above the final value. These four heats

must be regarded as having reached equilibrium within the limitations of the method.

Aluminum several times higher than the equilibrium value resulted in the formation of a thin and persistent scum of alumina covering the entire surface of liquid iron.

Heats 209, 210, and 211 indicate that by charging aluminum the time required for the attainment of equilibrium was reduced. Generally, heats were charged with an amount of aluminum slightly higher than the expected equilibrium concentration, and a period of time usually exceeding 8 hr was employed to reach equilibrium. Further increase in time was unjustified since the analysis for aluminum is not sufficiently precise to indicate small deviations from equilibrium.

Equilibrium Data: Table II gives the complete data on 20 equilibrium heats at 1695°, 1760°, and 1866°C. Tabulated also are values of the "apparent equilibrium constants" corresponding to Eqs. 1, 2, and 3, namely:

$$K_1' = [\% \text{ Al}]^2 [\% \text{ O}]^3$$

$$K_2' = [\% \text{ Al}]^2 \left(\frac{\text{H}_2\text{O}}{\text{H}_2} \right)^3$$

$$K_3' = \frac{1}{[\% \text{ O}]} \left(\frac{\text{H}_2\text{O}}{\text{H}_2} \right)$$

Thermodynamic Calculations

Oxygen: The equilibrium represented by Eq. 3 has been studied, at higher oxygen levels, by Dastur and Chipman.⁸ Theoretically, the activity coefficient of oxygen in each of the melts reported here is easily found by dividing the value of K_3' by their value of K_3 . This procedure, however, leads to extremely low values for the activity coefficient, so low, in fact, that the present authors are reluctant to put them forward. It seems possible that the results reported here, which are all at very low oxygen concentrations, may contain some small systematic error which makes these values of K_3' a little lower than they should be. In view of this possibility, no attempt will be made to correlate them with Dastur's data.

In Fig. 1 observed values of $\log K_3'$ at the two highest temperatures are plotted against the percentage of aluminum. Dastur's points are plotted

Fig. 1—Experimental values of $\log K_3'$ or $\log (\text{H}_2\text{O})/(\text{H}_2) [\% \text{ O}]$. Limits indicate effect of error of ± 0.001 pct in analysis for oxygen.

at zero aluminum but are ignored in drawing the lines.

The effect of an error of ± 0.001 pct in oxygen analysis is indicated to emphasize the sensitivity of the plot. Actual deviations should be ascribed as much to errors in gas composition as to oxygen analysis. Since the experimental values of $\log K_3'$ are not constant it is evident that the activity coefficient of oxygen varies with the concentration of aluminum. Previous work has shown that in the binary system Fe-O the activity coefficient is constant; hence, variations in the ternary system may be ascribed entirely to the effect of the third component. The slopes of the lines in Fig. 1 represent values of the coefficient $\partial \log f_o / \partial [\% \text{ Al}]$ which shall be designated here by the symbol $e_o^{(Al)}$. Since $\log f_o$ is zero in the absence of aluminum it follows that within the range of concentrations in which $e_o^{(Al)}$ is constant:

$$\log f_o = e_o^{(Al)} [\% \text{ Al}] \quad [4]$$

The slopes of the two lines of Fig. 1 yield values of $e_o^{(Al)} = -5.6$ and -8.0 at 1866° and 1760°, respectively; the data for 1695° agree roughly with those for 1760°. It is evident that the data do not yield accurate values of this quantity but that the figures given are conservative, for if the lines had been drawn to Dastur's points, the numbers would have been about doubled. The uncertainty is regrettable but is inherent in the very low concentrations involved.

Fig. 2—Effect of concentration on equilibrium product $[\% \text{ Al}]^2 [\% \text{ O}]^3$.

Interaction of Al and O: The attractive forces between dissolved atoms of aluminum and oxygen which give rise to the effect discussed above also lead to variation in values of the equilibrium product $[\% \text{ Al}]^2 [\% \text{ O}]^3$. Before examining the data on this product it will be helpful to review briefly the thermodynamics of ternary solutions which are very dilute with respect to two components.

For the limiting case of a solution which is infinitely dilute with respect to components 2 and 3 in the solvent 1, Wagner⁹ has introduced the coefficients

$$\epsilon_2^{(2)} = \partial \ln f_2 / \partial N_2 \quad [5]$$

$$\epsilon_2^{(3)} = \partial \ln f_2 / \partial N_3, \text{ etc.}$$

and has shown that

$$\epsilon_2^{(8)} = \epsilon_8^{(2)} \quad [6]$$

In the very dilute solutions which are the concern here, it is reasonable to assume that Eq. 6 remains valid and further that $\epsilon_{\text{Al}}^{(\text{Al})}$ and $\epsilon_{\text{O}}^{(\text{O})}$ are negligible. Variations in the activity coefficient of oxygen are ascribed entirely to the effect of aluminum and, reciprocally, variations in f_{Al} are regarded as effects of oxygen. The quantity $\epsilon_{\text{O}}^{(\text{Al})}$ or $\epsilon_{\text{Al}}^{(\text{O})}$ may be re-

Fig. 3—Effect of temperature on interaction parameter $e_{\text{O}}^{(\text{Al})} = d \log f_{\text{O}} / d [\% \text{ Al}]$.

garded as an interaction parameter which most conveniently represents the effect of one element on the thermodynamic behavior of the other. The parameter is expected to vary with temperature, but at constant temperature the value determined at infinite dilution may remain constant over a considerable range of concentration.

The coefficient $e_{\text{O}}^{(\text{Al})}$ used in the preceding section is related to $\epsilon_{\text{O}}^{(\text{Al})}$ in the manner that atom fraction is related to weight percent. Introduction of the necessary numbers reduces Eq. 6 to the following form which is valid within the composition range in which the e 's are constant:

$$e_{\text{Al}}^{(\text{O})} = \log f_{\text{Al}} / [\% \text{ O}] = \frac{27}{16} e_{\text{O}}^{(\text{Al})} \quad [7]$$

The equilibrium constant for the deoxidation reaction, Eq 1, may be expressed as follows:

$$K_1 = [\% \text{ Al}]^3 \cdot [\% \text{ O}]^3 \cdot f_{\text{Al}}^2 \cdot f_{\text{O}}^3$$

$$\log K_1 = \log K'_1 + 2 \log f_{\text{Al}} + 3 \log f_{\text{O}}$$

$$= \log K'_1 + 2e_{\text{Al}}^{(\text{O})} [\% \text{ O}] + 3e_{\text{O}}^{(\text{Al})} [\% \text{ Al}] \quad [8]$$

which, in view of Eq. 7, becomes

$$\log K_1 = \log K'_1 + 3.37 e_{\text{O}}^{(\text{Al})} [\% \text{ O}] + 3 e_{\text{O}}^{(\text{Al})} [\% \text{ Al}]$$

$$= \log K'_1 + 3 e_{\text{O}}^{(\text{Al})} (1.12 [\% \text{ O}] + [\% \text{ Al}]) \quad [9]$$

In Fig. 2 the experimental values of $\log K'_1$ are plotted against $(1.12 [\% \text{ O}] + [\% \text{ Al}])$. The slope of the line represents $3e_{\text{O}}^{(\text{Al})}$ at each temperature. The intercept would represent $\log K_1$ but a more representative value will be found after establishing average values of $e_{\text{O}}^{(\text{Al})}$ and $e_{\text{Al}}^{(\text{O})}$. The slopes of the three lines correspond to values of $e_{\text{O}}^{(\text{Al})}$ of -3.3 , -7 , and -10 at 1866° , 1760° , and 1695° , respectively.

The two sets of values of $e_{\text{O}}^{(\text{Al})}$ are plotted against temperature in Fig. 3. These are not entirely independent sets since both involve oxygen analyses. The first set derived from Fig. 1 depends upon gas composition, the second does not. An average line is extrapolated to 1600° and the best values of the

Fig. 4—Experimental values of $\log K'_2$ or $\log [\% \text{ Al}]^2 (\text{H}_2\text{O})^3 / (\text{H}_2)^3$.

coefficients at several temperatures are assembled in Table III.

It is interesting to compare the effects of aluminum on the activity coefficient with those of other elements that have been studied.¹⁰ Both chromium and vanadium diminish the activity coefficient of oxygen and are trivalent, like aluminum, and hence comparable. The order of arrangement of the three is the same as that of the heats of formation of the oxides. Table IV shows the comparison. In a very general way, the effect on the activity coefficient parallels deoxidizing power of the three elements as represented by the free energy change in reactions of the type of Eq. 3. The tabulated values are taken from ref. 10.

Aluminum in Iron: The effect of oxygen on the activity of aluminum has been shown in Table III. The corresponding effect on $\log K'_2$ is shown in Fig. 4 in which the lines are drawn with the slopes required by Table III. It is evident that the data do not afford accurate estimates of these slopes but that

Table III. Interaction Parameters of Aluminum and Oxygen in Liquid Iron

Fig. 6—Effect of temperature on the de-oxidation constant, $a_{Al}^2 \times a_o^3$.

again the effect is estimated conservatively since greater slopes would fit the data equally well.

The limiting values of $\log K_2'$ at zero oxygen represent $\log K_2$ at the three temperatures. It is obvious that these are subject to uncertainties of ± 0.5 or greater. Nevertheless, they are of interest as the only experimental values of this equilibrium constant. In Fig. 5 they are plotted against the reciprocal of absolute temperatures and compared with the calculated values of ref. 10. The calculated slope is probably better than could be obtained from the present data and this is used to draw the solid line whose equation is

$$\log K_2 = -42850/T + 10.37 \quad [10]$$

Eq. 10 deviates from the data of ref. 10 by about 0.6 in $\log K_2$. If this is attributed entirely to deviation in the gas composition, it is equivalent to 0.2 in the logarithm of the ratio $(H_2O)/H_2$, the values of this investigation being low by that amount. Similarly in Fig. 1 the deviations in $\log K_3'$ correspond to ratios that are low to the extent of 0.12 to 0.16 in $\log K_3$ at 1760° and 1866°, respectively. It is not possible at the present time to assign causes of this deviation nor to be sure that it resides in the gas composition.

Deoxidation Constant: Returning to Eq. 1, the equilibrium constant for the deoxidation reaction is calculated in Table V. This includes data on two heats in Table I which appear to have reached equilibrium as well as those in Table II. The average values of $\log K_1$ at each temperature are plotted in Fig. 6. The straight line, which represents the calculated line given in ref. 11, is fitted by the equation

$$K_1 = a_{Al}^2 \cdot a_o^3; \log K_1 = -64000/T + 20.48 \quad [11]$$

The agreement is surprisingly good. Although the new data indicate a slightly smaller temperature coefficient, they are not sufficiently accurate to warrant a change and the equation of ref. 11 is considered satisfactory as it stands. It must be noted that the equation applies to activities rather than percentage concentrations.

Table IV. Comparison of the Effects of Three Elements on Activity Coefficient of Oxygen at 1600°

	Chromium	Vanadium	Aluminum
$e_o^{(s)} = \partial \log f_o / \partial [\% X]$	-0.06	-0.25	-12

ΔF° for reaction $2X + 3O = X_2O_3$			
kcal at 1600°C	-32	-50	-117

Fig. 7—Comparison of data on aluminum deoxidation. Broken lines show oxygen activities at 1600° and 1866°. Curved solid lines are corresponding percentages. Experimental points at 1866° are shown. Data of Hilty and Crafts and of Wentrup and Hieber at 1600° are shown.

For comparison with other data on aluminum deoxidation, Eq. 11 is used to obtain an extrapolated value of K_1 at 1600° of 2×10^{-14} . This is thought to be a more reliable figure than could have been obtained by a direct experimental approach using our method. To obtain corresponding values for actual concentrations of aluminum and oxygen requires use of the extrapolated interaction parameters of

Table III together with Eq. 9. The results of this calculation are shown in Fig. 7 along with the experimental data for 1866°C. Experimental results of Wentrup and Hieber² and of Hilty and Crafts³ at 1600° are included. No attempt will be made here to account for the discrepancy.¹² The low activity coefficients provide only a small correction.

Summary

An experimental study has been made on the equilibrium of liquid iron containing aluminum and oxygen with a gaseous mixture of hydrogen and water vapor and with crucibles of pure Al_2O_3 at temperatures in the range 1695° to 1866°C. The results were used to obtain activity coefficients of aluminum and oxygen in the solution and the equilibrium constants of the several reactions.

The activity of oxygen is strongly reduced by the presence of aluminum and reciprocally oxygen reduces that of aluminum. The effect diminishes with increasing temperature.

Equilibrium constants are in approximate agreement with calculations based on data of "Basic Open Hearth Steelmaking." The "deoxidation constant," $a_{\text{Al}}^2 \cdot a_{\text{O}}^3$ is represented by the equation

$$\log K_1 = -64000/T + 20.48$$

The experimental values of the product $[\% \text{Al}]^2 \cdot [\% \text{O}]^3$ are much lower than results of Wentrup and Hieber or of Hilty and Crafts. The discrepancy is not accounted for by the low activity coefficients.

Technical Note

Low Temperature Aging in Titanium Alloys

by W. M. Parris, L. L. Hirsch, and P. D. Frost

IT has been established that titanium alloys containing sufficient amounts of β -stabilizing elements, such as iron, chromium, or manganese, can be age hardened.¹ Adenstedt, Pequignot, and Raymer² showed that age hardening occurred in a Ti-15 pct V alloy at room temperature after it was quenched from a temperature in the β -phase region.

During a recent investigation of the heat-treating characteristics of binary Ti-Mn and Ti-Cr alloys at Battelle, further evidence of low temperature aging was found. Appreciable hardening occurred in some of these alloys at aging temperatures as low as 212°F

(100°C). Indeed, the brief heating period employed for mounting metallographic specimens in bakelite resulted in hardening. It was felt that further information on this low temperature aging phenomenon would be of general interest in view of the large amount of work currently being done on titanium alloys.

The alloys examined in this investigation were arc-melted in a water-cooled copper crucible as $\frac{3}{4}$ -lb ingots. Du Pont Process A sponge was used as a base material. The arc-melted ingots were forged at 1700° to 1800°F (927° to 982°C) and hot rolled at 1450°F (788°C) to 14 gage (0.064 in.) sheet. Small specimens were heated in argon at 1742°F (950°C) for 30 min and quenched in various liquid media or air cooled. They were then mounted in a room-temperature-setting resin and given a metallographic

polish. After Vickers hardness determinations had been made on these specimens, they were heated in boiling water (212°F) for 45 min and again subjected to hardness tests. Results of these tests are plotted in Figs. 1 to 3. (Each point in the curves represents the average of at least three hardness determinations.) Also included in Figs. 1 and 2 are curves representing the effect of mounting in bakelite on the hardness of the series of Ti-Cr specimens. The maximum temperature attained during the curing of the bakelite mounts was 320°F (160°C). Upon

attaining this temperature, the mounts were rapidly cooled to room temperature.

It is evident that some hardening occurred in all of the alloys under all conditions of prior heat treatment when they were reheated to 212°F. Hardness increases in the water-quenched specimens were moderate, averaging about 25 VHN. However, specimens cooled at the lower rates (liquid-nitrogen quench or air cooled) exhibited hardness increases of over 100 VHN in some cases. The alloys which contain 5 and 8 pct Cr, or 5, 6, and 8 pct Mn, hardened considerably more than those of lower or higher alloy contents. With the exception of the water-quenched 8 pct Cr alloy, the hardnesses of the bakelite-mounted specimens agreed very well with those of the specimens aged at 212°F.

This work demonstrates that it is possible to introduce large increases in hardness in certain titanium alloys by heating in the range 200° to 300°F. The effects of variation in aging time and temperature on the hardness and other properties of the alloys described have not been fully investigated. Likewise, the study has been applied to relatively few alloys. The aging phenomenon warrants further investigation. It will certainly be of interest to those who have been using bakelite mounts for examining the microstructures of titanium alloys. However, it may be of greater future significance in processing alloys for structural applications.

The information in this note was obtained in research on titanium alloys being conducted at Battelle Memorial Institute for the Materials Laboratory of the Wright Air Development Center, Contract AF 33(038)-3736. Permission to publish the data is gratefully acknowledged.

Thermal Conductivity Method for Analysis of Hydrogen in Steel

by Bruce M. Shields, John Chipman, and Nicholas J. Grant

The vacuum tin-fusion method of analysis for hydrogen, developed by Carney, Chipman, and Grant, has been modified to permit the analysis of the evolved gases for hydrogen by means of a thermal conductivity cell. A properly prepared sample can be analyzed in 10 min with a probable error of ± 0.12 ppm. A study of various methods for storage of hydrogen samples shows that samples can be safely held in a dry ice-acetone bath as long as six days. Storage in liquid nitrogen is necessary for samples to be held one week or more.

THE vacuum tin-fusion method, as developed by Carney, Chipman and Grant,¹ is the only analytical procedure which has shown promise of being fast enough for use in the control of hydrogen during steelmaking. It was felt that further simplification and faster speed of operation could be effected by the use of thermal conductivity measurements for analysis of the gases evolved in the tin-fusion method. The application of conductivity measurements to the tin-fusion method is possible because: 1—the evolved gas is essentially a mixture of hydrogen, nitrogen and carbon monoxide with a hydrogen content usually over 50 pct, 2—the evolved gas is collected at a relatively low pressure, and 3—the thermal conductivities of CO and N₂ are practically identical while that of hydrogen is very much greater. The major part of this research program was devoted to the construction and calibration of a vacuum tin-fusion apparatus which analyzes the evolved gases for hydrogen by means of a thermal conductivity cell.

The second phase of the problem was associated with the development of a procedure for storage of samples prior to analysis. With the rapid quenching method for hydrogen sampling,² which seems to be the most practical for steel mill use, it is necessary that the samples be stored safely during the interval between sampling and analysis if the hydrogen content of the molten metal is to be maintained in the supersaturated solid samples.

The thermal conductivity bridge has been used for a number of years in the analysis of certain gas mixtures. An elementary discussion of the theory and practice of gas analysis by thermal conductivity measurements is given by Minter.³ A more comprehensive discussion of the theory and of the various measuring circuits is presented by Daynes.⁴ A complete knowledge of the theory and properties of

the thermal conductivity of gases and gaseous mixtures can be gained by a study of the standard textbooks on the kinetic theory of gases.⁵⁻⁷ The existing data on the thermal conductivity of single gases are reviewed by Hawkins,⁸ that for a number of binary gas mixtures by Daynes⁴ and Lindsay.⁹

The thermal conductivity method may be applied to the determination of the composition of a binary mixture if: 1—the thermal conductivity of the mixture varies monotonically with composition, and 2—the two gases have measurably different thermal conductivities. The greater the difference between the two gases, the greater the sensitivity of the method.¹⁰ The method is applicable to the analysis of multicomponent mixtures when all of the gases in the mixture except one have nearly the same thermal conductivity. Fortunately, the mixture of hydrogen, nitrogen, and carbon monoxide evolved by the tin-fusion analysis¹ falls in this latter classification. The thermal conductivities of nitrogen and carbon monoxide are practically equal; and the thermal conductivity of hydrogen is approximately seven times that of the other two. Therefore, the thermal conductivity of a gaseous mixture of hydrogen, nitrogen, and carbon monoxide at known temperature and pressure can be related directly to the percentage of hydrogen in the mixture by suitable calibration.

Usually the thermal conductivity of a mixture of gases is measured at atmospheric pressure where the thermal conductivity is independent of pressure over a wide pressure range. At very low pressures (below 1 mm Hg), the thermal conductivity of gases varies with the pressure. This phenomenon has been utilized in the Pirani vacuum gage for the measurement of pressures in the range of 10^{-1} to 10^{-6} mm of mercury.¹¹ Very little has been published concerning the variation of thermal conductivity with pressure at intermediate pressures between 1 mm Hg and 1 atm. However, preliminary measurements indicated that the thermal conductivities did vary with pressure over the range of pressures (up to 10 mm Hg) at which gases are delivered from the vacuum pump. Therefore, the calibration of the thermal conductivity cell had to be planned to include the effects of both gas composition and pressure. Such a calibration chart is shown in Fig. 4.

Most industrial applications of the thermal conductivity method of gas analysis have used a compensated Wheatstone bridge circuit containing two

or four-cell matched units.¹² Recently Ishihara and Sawa¹⁸ successfully applied a double cell circuit for measuring hydrogen extracted by high temperature vacuum fusion. However, the simplest and theoretically soundest method of measurement utilizes a circuit containing a single thermal conductivity cell¹⁴ maintained at constant temperature. The single conductivity cell circuit was adopted for the vacuum tin-fusion apparatus.

Apparatus

The major modifications to the apparatus of Carney, Chipman, and Grant were the elimination of the copper oxide furnace, the freeze-out traps, and the gas circulating equipment, and their replacement by a conductivity cell, a single cell conductivity bridge, and a mixing chamber. A diagram of the modified apparatus is shown in Fig. 1. Most of the essential parts have previously been described in detail by Carney, Chipman and Grant.¹ A brief description of the new parts is given below.

Known Volume: The known volume extending from the outlet portion of pump H_1 to point b on cut-off C_2 (excluding the conductivity cell) and to point d on cut-off C_2 is equal to 871 ± 2 cu cm.

Mixing Chamber: Previous investigators¹ have shown that the hydrogen in the gases evolved during tin-fusion tends to diffuse out sooner and faster than the carbon monoxide and nitrogen. It was noted in fact that the hydrogen which evolved first could collect in the higher portions of the apparatus while the other heavier gases settled in the lower section. Such a stratification could lead to erroneous thermal conductivity results in view of the rapid determinations made with this apparatus. To guard against such an occurrence, a mixing chamber was installed in the system, the details of which are shown in Fig. 2. Experiments with various gases introduced individually in varying orders showed that the mixing chamber eliminates any possibility of stratification.

Thermal Conductivity Cell: The bottom section of the cell is made of pyrex tubing, 1 cm OD and 8 mm ID, with a closed bottom and a female ground joint on the top, as shown in Fig. 2. The seal between the top and bottom sections is made with picein. A thin piece of pure platinum wire, 0.0104 mm (0.0041 in.) in diameter and approximately 16 cm long, is suspended in the center of the cell from

nickel wire supports. The wire is held taut by a small tungsten spring. The nickel supports are welded to the tungsten rods used to conduct the current into the cell through a glass-metal seal. The electrical leads from the Wheatstone bridge circuit are attached to the tungsten rods. The entire cell up to the side-arm is maintained at 0°C by immersion in an ice and water bath.

Wheatstone Bridge Circuit: In the single-cell thermal conductivity method, the conductivity cell is kept at constant temperature by immersion in ice and water, and the platinum wire is brought to the same temperature each time by the proper adjustment of the current through the wire. The current needed to maintain the wire at the specified temperature is determined by the rate of heat liberation from the wire, which is the same as the rate at which heat is carried away from the wire by gaseous conduction, provided that other sources of heat loss, such as conduction through the ends of the wire, radiation, and gaseous convection, are negligible. Thus the observed current is a measure of the conductivity of the gas.

A diagram of the single-cell thermal conductivity bridge is presented in Fig. 3. The large bridge rheostat P is set at a resistance such that when the bridge is balanced with pure hydrogen in the cell at the maximum pressure to be encountered, the current passing through the external circuit lies within the range of the precision ammeter A . To balance the bridge with a mixture of hydrogen and other gases at known pressure in the cell, the voltage across the ends of the bridge is adjusted by means of the coarse and fine rheostats Rh_1 and Rh_2 . The current recorded on the ammeter can be related to the gas composition after suitable calibration with mixtures of known composition and pressure. It will be noted that virtually all of the current measured by ammeter A passes through the conductivity cell because resistances P and R_2 are so much greater than R_1 and the cell, which has a resistance of approximately 3 ohms. Consequently, very little sensitivity is sacrificed by placing the ammeter in the external circuit where its resistance and temperature variations are not important.

Mercury Trap: The mercury trap between the mixing chamber and the conductivity cell was not originally built into the apparatus. During the calibration it was discovered that the mercury vapor in

Fig. 2—Detail of mixing chamber and thermal conductivity cell.

the vacuum system condensed on the wall of the conductivity cell because it was maintained at a lower temperature than the rest of the system. During a period of two weeks enough mercury condensed upon the wall of the conductivity cell to alter materially the shape of the calibration curves. Damage to the brazed joints was also noted from the mercury present in the cell. The installation of the mercury trap, which is maintained at -80°C by bubbling air through the dry ice-acetone mixture around the trap, eliminated the condensation of mercury vapor in the conductivity cell.

Calibration of Conductivity Cell

It has previously been mentioned that the conductivity of the gaseous mixture in the cell, as measured by the current supplied to the bridge circuit, is a function of both the pressure and the composition of the mixture. Thus, the conductivity cell had to be calibrated with pure gases and mixtures of known composition over a range of measured pressures. Calculations based on a sample size of 1 to 5 g and a hydrogen content in the steel of 1 to 25 parts per million (ppm) indicated that the calibration should cover a pressure range of 0.1 to 3.0 mm of mercury.

A calibration curve of pressure in millimeters of mercury versus conductivity reading in amperes was constructed for pure hydrogen by admitting different amounts of hydrogen into the system through the palladium tube, measuring the pressure in the known volume each time, and determining the current needed to balance the bridge for each pressure. Similar curves were determined for pure nitrogen and pure carbon dioxide by introducing various amounts of the purified gases into the system through the calibrating pipette. The calibration curves are shown in Fig. 4. Because the thermal conductivities of nitrogen and carbon monoxide are practically equal, the calibration curves for the two pure gases are of the same shape and so close together that they can be considered identical. Similar

calibration work with gas mixtures of known compositions showed that direct interpolation between the pure gas calibration curves is possible for gas mixtures. Thus a family of calibration curves for mixtures of hydrogen, carbon monoxide, and nitrogen was plotted from 0 to 100 pct H_2 by interpolation between the pure hydrogen curve and the curve representing pure nitrogen (and/or carbon monoxide).

Analytical Procedure

The clear silica crucible is initially charged with about 130 g of chemically pure tin sticks and 0.7 g of purified silicon metal. The crucible is placed in the bottom furnace section, the entire furnace section is assembled, and the system is evacuated. The furnace is gradually heated up to 1050°C and then "baked out" at this temperature for 2 hr. The degassing time and temperature needed for a low blank have been materially reduced by the use of clear silica crucibles and stick tin as compared to using the satin finish silica.

After the completion of the degassing period, the conductivity circuit is standardized. A small amount of hydrogen is admitted to the system through the palladium tube, the pressure of the hydrogen in the known volume is measured with the McLeod gage, and the hydrogen is permitted to enter the conductivity cell. With pure hydrogen at known pressure in the cell, the current is turned on and bridge rheostat P, Fig. 3, is adjusted so that, with the bridge balanced, the ammeter reading corresponds to the proper reading for that particular pressure on the pure hydrogen calibration curve. At the completion of the standardization, the cell is turned off and all cut-offs are lowered to evacuate the system in preparation for a blank determination. Normally standardization is only necessary at the beginning of a day's run unless there is reason to suspect that the batteries are becoming weaker or the ambient temperature of the instrument panel changes markedly.

The blank is measured by collecting furnace gas in the known volume for 5 min. The pressure of the blank gas is measured by the McLeod gage, and the percentage of hydrogen in the gas is determined in the conductivity cell. At the completion of the blank determination all the cut-offs are again lowered in preparation for the first analysis.

The metal sample is washed in carbon tetrachloride, dried in a current of dry, oil-free air, and weighed on an analytical balance. It is forced beneath the surface of the mercury reservoir and permitted to float to the top of the mercury column. A strong magnet is used to move the sample over to the furnace head. After cut-offs C_2 and C_3 are raised and the gas mixer is turned on, the sample is dropped into the furnace. At the end of the 5-min collection time, cut-off C_1 is raised and cut-offs C_2 and C_3 are adjusted to points b and d respectively. The pressure of the collected gas in the known volume is measured with the McLeod gage, preferably in two of the three calibrated sections to detect any water vapor in the gas.* Cut-off C_2 is lowered to

* Normally water vapor is only present when samples are improperly dried before analysis or when hollow samples contain water picked up during quenching.

permit the gas to enter the conductivity cell and is then raised to point c. The conductivity cell is turned on and the bridge circuit balanced by the proper adjustment of coarse and fine rheostats Rh_1 and Rh_2 . The percentage of hydrogen in the gas can

be read off the calibration chart by utilizing the ammeter reading and the previously measured pressure. The conductivity cell is turned off before the cut-offs are again lowered to prevent overheating of the wire in the cell when it is evacuated. All cut-offs are lowered to exhaust the system in preparation for the next analysis.

Evaluation of the Method

Blanks: After an initial 2-hr bake-out period at 1050°C, the 5-min blank value was reduced to about 0.08 ppm for a 2-g sample. The average 5-min blank correction during the analysis of 50 samples with an average weight of 2.9 g was 0.08 ppm. Blank values were determined several times during a day's run and generally showed a gradual decrease throughout the day.

Evolved Gases: A comprehensive discussion of the gases evolved in the tin-fusion method has been presented by Carney, Chipman, and Grant.¹ The gases evolved from the samples analyzed in this study had hydrogen contents of from 65 to 98 pct by volume and averaged close to 90 pct by volume.

Time for Analysis: The time required for the actual analysis of a single sample is 10 min, although in routine use a total time of 15 min per sample is required to allow for sample preparation, weighing, and introduction of the sample into the melt. The total time required to analyze samples on a routine basis can be further reduced from 15 to 12 min per sample by the use of a direct weighing balance and the installation of a faster McLeod gage. However, the 15-min analysis possible with the present apparatus puts it within the range of many steel mill control analyses.

Precision: The overall precision of analysis by the thermal conductivity method was evaluated by the use of duplicate samples. Each of 10 samples, obtained from a molten bath in the manner described by Carney, Chipman, and Grant,² was cut in half to provide 10 sets of duplicate samples for analysis. The small size of the samples and the sampling technique make it safe to assume that the two halves of each sample contained equal percentages of hydrogen. The results of the analysis of these duplicate pairs by the tin-fusion method in the thermal conductivity apparatus are summarized in Table I. A statistical analysis of the data from these 10 pairs shows the standard deviation of the error of observation to be ± 0.17 ppm. The probable error is ± 0.12 ppm. Using the statistical criterion of three standard deviations, the error in 95 pct of all analyses will be less than ± 0.5 ppm. It should be emphasized that this precision was obtained with 2 to 3-g samples containing approximately 6 ppm of hydrogen. Greater precision can be obtained when analyzing larger samples.

Storage of Hydrogen Samples

With the rapid quenching method for hydrogen sampling,² which preserves the hydrogen content of the molten metal in the supersaturated solid samples, it is necessary that the samples be properly stored to maintain the hydrogen content during the interval between sampling and analysis. Hydrogen is an extremely mobile element and will diffuse out of supersaturated steel samples at room temperature in a relatively short time. Even though the addition of alloying elements to steel may retard the release of hydrogen from quenched samples and although the effusion of hydrogen is slower from austenitic steels than from pearlitic or ferritic steels,¹⁵ it is not

Fig. 4—Calibration curves for conductivity cell.

possible to maintain the hydrogen content of most liquid steels in a quenched sample for any length of time at room temperature. The work by Carney, Chipman, and Grant² includes a complete discussion of storage methods utilized by other investigators together with their own observation that samples could be stored in dry ice for periods of time up to 24 hr with negligible loss of hydrogen. Of the many methods used by previous investigators for either preventing the effusion of hydrogen from the samples or collecting the hydrogen which does diffuse out, the simplest and most practical is the immersion of the samples in a medium at such a low temperature that the diffusion of hydrogen is virtually stopped. It was the purpose of this investigation to determine what storage temperature was necessary to inhibit effectively the effusion of hydrogen from steel samples and how long the samples could be stored at this temperature before a measurable loss of hydrogen occurred.

The samples for this investigation were obtained from heats melted in the controlled atmosphere furnace previously described in detail,² under a mixture of 5 to 10 pct H₂ and the balance helium. The details of the sampling procedure, utilizing a modified Taylor sampling device, have also been described. After thorough quenching in water and then in a dry ice-acetone bath some of the samples were stored in a dessicator at room temperature,

some in an ice and water bath, some in a dry ice-acetone mixture, and the rest in liquid nitrogen.

Prior to analysis, the samples were removed briefly from the storage baths one at a time and cut into 2 to 4-g specimens on an underwater cut-off wheel filled with ice water. After cutting, the specimens were dried and returned to their original storage bath. Throughout the cutting operation suitable precautions were observed to prevent contamination of specimens with grease, oil, or other materials likely to contain hydrogen.

The samples were analyzed according to a time schedule which depended upon the particular storage method being investigated. The results of the analyses for the four storage methods are shown in Tables II to V.

The data in Table II show that it is not safe to keep quenched hydrogen samples at room temperature. The ferritic Armco iron samples used in this investigation showed a gradual decrease in hydrogen content beginning almost immediately after the quenched samples had reached room temperature.

Storage in an ice-water mixture does not retain

the hydrogen content much better than does room temperature storage. The analyses reported in Table III indicate that hydrogen samples cannot be stored even one day at 0°C without losing an appreciable portion of their hydrogen content.

It is apparent from the data in Table IV that storage in a dry ice-acetone mixture is satisfactory for periods of time up to six days. If samples are to be stored for as long as a week or more, they must be kept in liquid nitrogen.

It should be emphasized that the results quoted in this study were determined only for Armco iron samples containing about 6 ppm of hydrogen.

Summary

The vacuum tin-fusion method of analysis for hydrogen, developed by Carney, Chipman, and Grant, has been modified to permit the analysis of the evolved gases for hydrogen by means of a thermal conductivity cell. The major advantages of the thermal conductivity method are: 1—elimination of the often questionable conversion of hydrogen to water vapor in the copper oxide furnace, 2—simplification of apparatus, and 3—increased speed of analysis. A properly prepared, weighed sample can be analyzed in 10 min with a probable error of ± 0.12 ppm of hydrogen.

A study of various methods for storage of hydrogen samples shows that samples can be held in a dry ice-acetone bath as long as six days with negligible loss of hydrogen. Storage in liquid nitrogen is necessary for samples to be held one week or more.

Acknowledgments

The authors wish to express their appreciation to W. W. Harvey for his help in the design and construction of the thermal conductivity apparatus and to the Office of Naval Research for sponsorship of the research program (Contract No. N5ori-07816, Task No. XVI NR-031-186).

Reduction of Silicon from Blast Furnace Type Slags

by James C. Fulton, Nicholas J. Grant, and John Chipman

This paper contains data on the distribution of silicon between liquid iron-silicon-carbon alloys saturated with respect to graphite and $\text{CaO-SiO}_2\text{-Al}_2\text{O}_3$ slags under 1 atm of CO at 1600°C . The ranges of slag compositions studied were extended from the dicalcium silicate saturated liquidus composition up to silica concentrations at which SiC appeared as a stable phase.

IN blast furnace operation it is not to be expected that slag and metal reach equilibrium with one another. Nevertheless, the silicon content of the metal varies with slag composition and with temperature in a manner which would be predicted from equilibrium considerations. Similarly, the distribution of sulphur between slag and metal does not attain an equilibrium state, yet the influence of slag composition is strongly analogous to its effect on the distribution equilibrium.

The desulphurizing power of metallurgical slags has been shown to be highly dependent upon the FeO content of the slag. Moreover, the rate of removal of sulphur from slags is influenced by the oxygen potential of the slag-metal system. Thus it was shown by Grant, Kalling, and Chipman¹ that the presence of MnO in slags which are low in FeO causes a marked slowing down of the transfer of sulphur from metal to slag.

This led to the hypothesis that the slow removal of sulphur by blast furnace slags of more acid composition might be due in part to the effect of SiO_2 on the oxygen potential of the system. This was verified in the work of Grant, Troili, and Chipman,² who found that the desulphurizing power of the more acid blast furnace slags could be markedly improved by an increase in the silicon content of the underlying metal. Their explanation of this improvement was that the higher silicon content of the metal decreased the rate of transfer of more silicon and, along with it, of oxygen from the slag to the metal. The slowness of the transfer of sulphur from metal to slag was the result of the slow reduction of SiO_2 from slag to metal. Attempts to study the rate of sulphur removal had in the past resulted in very slow rates corresponding to the rates of silica reduction. It has become evident on the basis of these

studies that further experimental studies on the rate of removal of sulphur must take these factors into consideration if there is to be a clear understanding of the rate of sulphur transfer under conditions simulating those existing in the blast furnace. It will be necessary, at least in a part of such study, to employ combinations of slag and metal in which

Fig. 1—Schematic drawing of graphite crucible and stirrer.

the disturbing effect of silica reduction has been eliminated; in other words, to employ slag-metal combinations which are already in equilibrium with respect to the transfer of silicon.

In preparation for such studies of desulphurization, a preliminary program of research on the distribution of silicon between slag and metal has been undertaken. This will ultimately include a comprehensive survey of the effects of temperature and slag composition on the equilibrium distribution of silicon between slag and metal. The present paper is a report on experimental methods employed and on

the results obtained in one series of slag compositions at 1600°C.

Experimental Procedure

The furnace used in this investigation has been adequately described.⁸ The crucible design, initially modified by Grant, Kalling, and Chipman,¹ was used in the first 42 heats of the current study. Beginning with heat 43, the crucible and stirrer arrangement shown in Fig. 1 was substituted. The new design was shown to have not only good thermal characteristics, but also somewhat better mixing qualities.

The temperature of the present set-up is controlled by sighting an optical pyrometer down through the hollow stirring rod and into a centrally drilled $\frac{3}{8}$ in. diam hole in the stirrer. The hole ends 1 in. from the bottom of the stirrer at a point just below the slag-metal interface. By means of a Pt-Pt-Rh thermocouple inserted into the crucible while the stirrer was turning at the usual rate of 600 to 800 rpm, it was found that a temperature difference of not more than 6°C exists between the bottom of the crucible and upper slag surface. Similarly, a thermocouple placed in the pyrometer sighting hole checked the temperature of the optical pyrometer within $\pm 2^\circ\text{C}$. These calibrations served to substantiate the accuracy of the temperature measurements and reaffirm the conclusions of previous investigators who used this apparatus. The main source of temperature fluctuation was the normal variation in control of the induction furnace, yielding a maximum deviation of $\pm 10^\circ\text{C}$ throughout a heat.

The metals used in the heats are listed in Table I. The Armco iron punchings have been used throughout all runs while the source of silicon has changed. In the study of the CaO-SiO₂ slags, silicon metal (A) was used in heats 5, 6, 7, 8, 9, and 12 while silicon metal (B) was used in the remainder of these heats. For the CaO-SiO₂-Al₂O₃ slags, silicon metal (A) was used in all heats up to 97, at which time a 44 pct silicon ferro-alloy was prepared with Armco iron and

* Zero time is taken as that time when the slag and metal are first judged to be molten and at the reaction temperature. The time listed is the time after zero time.

silicon metal (B). This alloy was used in all subsequent heats.

The slags were made by mixing master slags which had been prefused in a graphite crucible. Actual chemical analyses after fusion were used in calculating the various quantities desired.

The "zero-time" used in the tables and figures is a somewhat ambiguous quantity since liquid metal and liquid slag were not mixed to start a run. Si and SiO₂ analyses tended to stray from the calculated composition when samples were taken prior to half an hour after all constituents were in the crucible at 1600°C. For the first 101 heats, about half of the

slag and all the metal were placed in the crucible and heated to 1600°C in an atmosphere of carbon monoxide which was purified by passing over ascarite and anhydron. (Nominal gas purity was 97 pct CO, 3 pct N₂.) Generally, it required 15 min to heat the charge to 1600°C and about 10 min more for it to melt in so that the remaining portion of the slag could be added. "Zero-time" for the first 101 heats was taken as that time when all the slag and metal were in the crucible and at the reaction temperature. This is obviously not "zero" reaction time.

Beginning with run 102, a change in melting procedure was made to try to reduce the length of time necessary to fuse the slag as well as to help stabilize the initial silicon analysis. The new procedure consisted of melting only the metal in a nitrogen atmosphere and allowing 5 to 10 min for graphite saturation. All the slag was then added within 5 min, and as soon as the system reached the reaction temperature, the run was considered started. In this procedure the CO atmosphere was established simultaneously with the slag addition. "Zero-time" was again taken when all constituents reached the reaction temperature.

The course of the reaction was followed by slag and metal samples removed during a run. The slag samples were solidified on the end of an iron rod and metal samples were drawn up into a Vycor tube with an aspirator bulb. Slag and metal samples were crushed to -100 mesh. Iron particles were removed from the slag by a hand magnet prior to analysis.

Reaction Studied

The chemical reaction under investigation is given in Eq. 1:

The SiO₂ was dissolved in a CaO-SiO₂ or CaO-SiO₂-Al₂O₃ slag. The metal phase consisted of Fe and Si saturated with graphite.

If a system is considered which is composed of a CaO-SiO₂ slag and the corresponding metal, there are five components and four phases. The components are Ca, Si, O, Fe, and C. The phases are slag, metal bath, gas, and graphite. According to the phase rule this yields two degrees of freedom in a constant pressure system. Thus, if the temperature and the percentage of silicon is fixed, the equilibrium state of the system will be completely described.

Fig. 2 shows schematically how the reaction progresses. Assume line AB represents the equilibrium distribution of Si and SiO₂ at a given temperature. If the initial composition E is selected, there will be silica reduction; that is, Eq. 1 shows a net reaction toward the right (increasing silicon in the metal) along a path such as 1 or 2 in Fig. 2. If an initial composition such as D is selected, there will be silicon oxidation, and Eq. 1 will show a net reaction to the left (increasing SiO₂ content) indicated by path 3 or 4. The steepness of the path from the initial composition depends on the relative quantities (weights) of the two phases charged. Paths 2 and 3 represent higher weight ratios of metal to slag than paths 1 and 4.

Finally, it may be pointed out that these paths are not straight. As the reaction proceeds in either direction, there is a transfer of material between the slag and metal phases tending to increase the weight of the one relative to the other. When silica reduction occurs, there is a loss of 1 g of SiO₂ from the slag for each gain of 28/60 g of silicon in the metal.

† CO bubbled through metal and slag, in all other heats CO flushed over slag surface.

Fig. 3—Silicon distribution at 1600°C for Fe-Si-C alloys saturated with graphite and in contact with CaO-SiO₂ slags under 1 atm of CO. CO gas flushed over slag surface.

Since the iron is saturated with graphite, the only change of percentage of carbon in the metal is that due to the corresponding change of percentage of silicon. In other words, carbon changes due to solubility effects, not stoichiometric considerations.

Results and Discussion

The results of chemical analyses of slag and metal samples taken from heats held at 1600°C are shown in Tables II, III, and IV and are plotted in Figs. 3, 4, and 5 for 0, 10, and 20 pct Al₂O₃, respectively. The final compositions of the binary slags of Fig. 3 are those listed in Table II. The ternary slags of Figs. 4 and 5 have been corrected to even 10 and 20 pct Al₂O₃ as explained below. From preliminary curves similar to Figs. 4 and 5 it was evident that an increase from 10 to 20 pct Al₂O₃ led to a corresponding decrease of from 2 to 7 pct SiO₂, depending on the silicon level. In plotting the final points, therefore, a proportional adjustment was made in the percentage of SiO₂ to correspond to exactly 10 or 20 pct Al₂O₃. This adjustment was not made in the initial points.

Chemical analyses have shown the usual variations for this type of determination. In run 12, Table II, duplicate samples were taken at 18, 23, and 24 hr. The silicon analyses showed a maximum deviation of 0.44 pct Si and the only slag pair that was ana-

Fig. 4—Silicon distribution at 1600°C for Fe-Si-C alloys saturated with graphite and in contact with CaO-SiO₂-10 pct Al₂O₃ slags under 1 atm of CO.

lyzed in duplicate indicated a deviation of 0.05 pct SiO₂. In run 31, Table II, the silicon dropped 1.06 pct Si from sample 2 to 3 in a run that is not changing composition according to the slag analysis. Thus, there are rather wide variations of results possible due to experimental errors. A more dependable measure of the limits of error can be found in time-averages of the Si and SiO₂ analyses. In general, these plots indicate a deviation of ±0.20 pct Si and ±0.30 pct SiO₂ for any one run.

Material balances on some of the runs indicated serious discrepancies between the SiO₂ lost from the slag and the Si gained by the metal. Table V shows the result of such balances made on runs 5, 8, 9, and 12 (see Fig. 3 and Table II). The charge compositions of slag and metal were taken as the initial conditions. From the final SiO₂ analyses, corresponding

† See Table III.

Si analyses have been calculated, neglecting the weight of slag and metal removed by sampling. Even such checks had limited value. For example, 5 and 12 lost slag due to copious CO evolution which frothed the slag into the system above the crucible. Run 12 is also low in Si for the additional reason that silicon carbide formed as one of the stable phases, as will be explained later.

Pin-pointing the initial composition has been a tedious problem. There are a number of factors that contribute to this uncertainty: 1—lack of homogeneity of master slags, 2—contaminated crucibles from previous runs, 3—dusting losses of slag, 4—errors in weighing, and 5—contamination of metal by entrapped slag. In view of these experimental difficulties, the first sample analyzed, instead of the charged composition, was plotted as the initial composition in Figs. 3 to 5, except when the results extrapolated back to the calculated composition. The final compositions are those listed in Tables II to IV.

It is important that significant chemical changes are detected, for it is the direction of the change as well as the final composition that determines the position of the curves. The greatest difficulty in interpolation of the curves in Fig. 3 to 5 was due to the broad gap remaining between the very slowly converging points from two sides. Silica reduction and silicon oxidation are very slow processes, even at concentrations rather far removed from equilibrium when from 8 to 24 hr were taken to approach equilibrium with vigorous stirring of the slag and metal. This was well illustrated in the curves shown by Grant, Troili, and Chipman.³ Probably the most significant factor in limiting the accuracy of the distribution curves in Figs. 3 to 5 is this sluggishness of the reaction. It seems to place the limits of the distribution curves at ± 1 pct SiO₂ at a given silicon concentration.

The range of SiO₂ concentrations available for study in this investigation were found to be determined by two factors. At the low SiO₂ end, the study was terminated by the liquidus compositions at which dicalcium silicate precipitates. The arrows pointing downward on the abscissas of Figs. 3, 4, and 5 at 42, 36, and 29 pct SiO₂, respectively, represent the liquidus compositions as read from the CaO-SiO₂-Al₂O₃ phase diagram.⁴

As SiO₂ was increased to the upper limit, it was found that the system became saturated with respect to silicon carbide (SiC) when the metal contained 23.0 pct Si, according to the reaction:

The SiC has been identified by X-ray patterns of specimens from the slag and metal and by metallographic examination of metal specimens. Comparison with previous studies on the structure of SiC⁵⁻⁷ revealed that the β modification was formed. It appeared in various colors with blue and green predominating.

The addition of another phase (SiC) to the system, in addition to those listed above, decreases the number of degrees of freedom by one. For the binary

Fig. 5—Silicon distribution at 1600°C for Fe-Si-C alloys saturated with graphite and in contact with CaO-SiO₂-20 pct Al₂O₃ slags under 1 atm of CO.

slags (Fig. 3), there is now only one degree of freedom, namely, temperature. For the ternary slags (Figs. 4 and 5), two degrees of freedom remain, namely, temperature and percentage of Al₂O₃. By fixing the temperature and percentage of Al₂O₃ at 0, 10, and 20 in Figs. 3, 4, and 5, respectively, these systems are completely described. The data are summarized in the three curves of Fig. 6 which extend from the dicalcium silicate liquidus to termini at 23 pct Si, where SiC appears.

It is interesting to compare the present data with the electrochemical study of Chang and Derge.⁸ Briefly, their experimental apparatus consisted of a silicon carbide electrode dipped into a slag held in a graphite crucible. The electromotive force between the graphite and silicon carbide was taken as a measure of the silica activity in the slag. Fig. 7 shows a summary of their data at 1600°C where they have plotted iso-electromotive force (iso-activity) lines as a function of slag composition.

In order to get some comparable results from the present study, it is necessary to return to Eq. 1 and the corresponding equilibrium constant which is

$$K_1 = \frac{a_{\text{Si}} p_{\text{CO}}^2}{a_{\text{SiO}_2}}$$

Since the metal is saturated with carbon, and the

pressure of carbon monoxide is constant, any alloy with a given silicon content will have a fixed silicon activity. Thus, if the slag compositions for constant silicon concentration in the metal are picked off Figs. 3 to 5, these points will represent constant silica activities. In this way, lines of constant silica activity corresponding to constant silicon concentrations have been superimposed on the results of Chang and Derge in Fig. 7. It is evident that no agreement exists between the two sets of data. It is the authors' view that the disagreement stems from the interpretation which Chang and Derge put upon their data. A more detailed discussion seems premature at this time and will be deferred until after publication of current work on the activity of silicon in Fe-Si-C alloys.

Based on the lines representing our results in Fig. 7, the following statements may be made concerning the activity of SiO_2 : 1—at constant percentage of silica, its activity increases with increasing Al_2O_3 and decreases with increasing CaO ; 2—the activity of SiO_2 is strongly dependent upon the lime:silica ratio. At a ratio of about 55:45 it is independent of Al_2O_3 or other composition variables. At lower ratios it is decreased and at higher ratios increased by addition of Al_2O_3 . Lines of constant lime:silica ratio have been constructed on Fig. 7 to show this relation.

The question of the rate-controlling step in reaction 1 has been raised by Darken⁹ with respect to the retarding action of SiO_2 reduction on desulphurization in blast furnace type slags. It was suggested that perhaps the rate is controlled by lack of gas bubble nucleation at the slag-metal interface. While most of the heats have been made with CO gas flushing over the slag surface, a sufficient number have been made in which CO was bubbled through the slag and metal in order to be able to detect any appreciable differences. All heats in Fig. 3 had CO flushing over the surface, while a differentiation of the method of gas entrance was made for the heats in Figs. 4 and 5. Qualitatively it appears that there was no improvement of rate by provision of artificial gas bubble nuclei. The similarity of results may be due to the intimate mixing of metal, slag, and gas by the stirring mechanism.

Sawamura and Sawamura¹⁰ recently published some results for the equilibrium of liquid pig iron with $\text{CaO-SiO}_2\text{-Al}_2\text{O}_3$ slags containing 10 pct Al_2O_3 . These workers used small heats consisting of approximately 15.5 g of metal and 6 g of slag. A graphite crucible containing the melt was quenched in water at the end of a run. Their results were not tabulated; however, the plot of a run at 1600°C indicated that equilibrium was obtained with 3.3 pct Si for a slag containing 44 pct SiO_2 , 46 pct CaO , and 10 pct Al_2O_3 . In the present investigation, this same slag was found to require 20.7 pct Si. From their graph it is obvious that silica reduction is still in progress at the end of 4 hr, but they relied on the more slowly changing silicon analyses. It is also worth noting that Sawamura and Sawamura did not stir their heats. This immediately suggests that diffusion of silicon in the metal or of silica in the slag may have been the rate-controlling step.

Conclusions

The results of this investigation may be summarized as follows:

1—The distribution of silicon between graphite-saturated Fe-Si-C alloys in equilibrium with CaO-SiO_2 and $\text{CaO-SiO}_2\text{-Al}_2\text{O}_3$ slags containing 10 and 20 pct Al_2O_3 has been established at 1600°C under 1 atm of CO.

2—The range of silica compositions amenable to study was found to be limited at the high silica concentrations by the formation of β silicon carbide and was extended to the liquidus composition in the low silica slags.

3—Lines of constant silica activity, corresponding to constant silicon in the metal, disagree with conclusions of Chang and Derge based on electromotive force measurements.

4—The silicon of the metal increases as alumina replaces lime at a constant percentage of silica. It is also highly dependent on lime:silica ratio.

Attainment of Equilibrium in Gas-Metal Reactions

by Nev A. Gokcen

EQUILIBRIA in the reactions between gases and liquid metals have been the subject of many interesting investigations. The experimental realization of true equilibrium, however, is questionable in certain cases due to the lack of conclusive studies in reaction rates. It will be shown here that a systematic interpretation of rate studies with the analysis of prevailing experimental conditions leads to valuable practical information.

The reactions of particular interest are:

The usual and perhaps the most convenient method of investigation may be illustrated with reaction 1. A stream of gas mixture consisting of $\text{H}_2 + \text{H}_2\text{S}$ is passed over or bubbled through the liquid metal at constant temperature. The ratio of $\text{H}_2\text{S}/\text{H}_2$ in the entrant mixture is fixed in each experimental run, and, therefore, the composition of melt varies until the establishment of equilibrium.

The purpose of this paper is to derive a formula

expressing the minimum time required for the establishment of equilibrium and to compare the calculated values from such a formula with the available data.

Equations

Reaction 1 is used for the purpose of illustrating the derivation. Let E represent the equilibrium and X the nonequilibrium sulphur in weight percent at any time t in minutes. For the sake of simplicity, it is first assumed that $E > X$ although the results are of general applicability without restriction. It has been shown by Morris and Williams¹ that within a difference of 1 pct S or less, i.e., $E - X \leq 1.00$, the value of $K'_1 = P_{\text{H}_2\text{S}}/P_{\text{H}_2} \cdot \text{S}\%$ is very nearly constant. The maximum ratio of available $P_{\text{H}_2\text{S}}/P_{\text{H}_2} = \text{H}_2\text{S}/\text{H}_2$, from which sulphur can be absorbed by metal, is equal to $\text{H}_2\text{S}/\text{H}_2$ in equilibrium with E (which equals $\text{H}_2\text{S}/\text{H}_2$ in the entrant gas), minus $\text{H}_2\text{S}/\text{H}_2$ in equilibrium with X . Thus:

$$\text{Available } \text{H}_2\text{S}/\text{H}_2 = EK'_1 - XK'_1 \quad [4]$$

Eq. 4 expresses that sulphur can be absorbed by metal from the $\text{H}_2\text{S}/\text{H}_2$ in the entrant gas until the gas leaving the metal assumes a value of $\text{H}_2\text{S}/\text{H}_2$ which is in equilibrium with the dissolved sulphur X at that time.

H_2S constitutes up to approximately 1 pct of the gas mixture. Its disassociation into H_2 and S_2 is about 1 pct at 1600°C , hence, the $\text{H}_2\text{S}/\text{H}_2$ impinging on the surface of metal is very close to that in the entrant gas. The rate of flow of hydrogen entering the reaction chamber is kept constant experi-

Fig. 1—Reaction rate at 1615°C. Upper curves $H_2S/H_2 = 0.00304$; lower curves $H_2S/H_2 = 0.00220$.

mentally. This is equal to the hydrogen passing through the entire apparatus, because the variation in the amount of hydrogen due to the reaction of part of H_2S with metal is extremely small. Let L represent liters of hydrogen (measured at 0°C and 1 atm) passing through the apparatus. Eq. 4 multiplied by L is equal to the available H_2S in liters per min from which:

$$\text{grams of S available per min} = \frac{32L}{22.4} K'_1 (E - X) \quad [5]$$

is obtained.

It should be emphasized that Eq. 5 represents the maximum amount of sulphur that can be absorbed per unit time by the metal containing X pct S at the time t . The minimum time required to reach equilibrium can be calculated by assuming that the maximum rate of sulphur transfer prevails, i.e.:

$$\frac{32L}{22.4} K'_1 (E - X) = \frac{W}{100} \frac{dX}{dt} \quad [6]$$

where W is the weight of metal in grams and dX the infinitesimal change in composition as the result of sulphur transfer. By rearranging Eq. 6 and integrating with $X = X_0$ when $t = 0$, the following general expression is obtained:

$$\log \frac{E - X_0}{E - X} = \frac{62.1 \times L}{W} K'_1 t \quad [7]$$

It is obvious that for $E = X$ the required time is infinity. Theoretically, this is correct but on account of the limitations in experimental methods, the attainment of equilibrium within 95 to 99 pct of the ideal E value is satisfactory and would require a finite or usually limited period of time. Eqs. 4 and 7 are not limited to the condition of $E > X$; they are also applicable in the exact forms above when $E < X$. It is noteworthy that the algebraic values of Eq. 4 and dX/dt are both negative when $E < X$, and then the value of the former represents H_2S absorbable by the entrant gas or simply the available H_2S/H_2 from the metal.

Applications

Morris and Williams¹ and Morris and Buehl² investigated reaction 1 very carefully by bubbling mixtures of $H_2S + H_2$ through the liquid iron at a rate of 1050 ml per min measured at room temperature (970 ml at standard temperature and pressure). They studied the rate of approach to equi-

librium with melts containing various elements and showed conclusively that the approach to equilibrium is a fairly slow process. During an experimental run, hourly samples of 2 g were taken from the metal, therefore, the weight of melt was constant only between the two successive samples. The weight loss due to splashing was variable, but in general negligibly small for the purpose of these calculations. Table I shows the results based upon their data in the region where the effect of experimental errors in percent sulphur upon Eq. 6 is small; that is, up to 0.98E or 0.99E in sulphur contents. Their data, substituted in Eq. 7, yield:

$$\log \frac{E - X_0}{E - X} = 3.61 \times 10^3 \frac{K'_1}{W} \theta$$

where $\theta = t/60$.

The results are plotted in Fig. 1 together with the original curves of the investigators. The agreement between the calculated and actual curves is remarkably good and, with the exception of the two upper curves, the difference is equivalent to 0.01 pct S or less, which is within the average analytical accuracy of the results. A better agreement between the two curves for run No. E-39 may be obtained by taking the initial sulphur 0.02 pct higher. The choice of the same initial composition and time for both the calculated and actual curves reflects the errors in the initial analysis upon the succeeding experimental points.

The agreement shows that the bubbling technique provides very nearly the maximum rate of sulphur transfer expressed by Eq. 6. Morris and Buehl² actually realized this fact and pointed out that nearly all of the available H_2S reacted with the liquid metal.

Table I. Minimum Time Required for the Change of Composition Toward Equilibrium in the Experiments of Morris and Williams

Run No.	Pct S, $X_{\uparrow\uparrow}$	Time, Hr	
		Actual $\uparrow\uparrow$	Calculated, θ
E-29 (Equil. S=0.86*) (Initial W=61.35 g**)	0.684	0.08	0.08
	0.775	2.56	2.11
	0.801	3.75	3.09
E-29 (Equil. S=0.50*) (W=55.65 g at 4.26 hr)	0.741	4.25	4.25
	0.624	5.25	5.26
	0.576	6.25	5.98
	0.538	7.25	6.96
	0.521	8.37	7.77

	1.305	1.25	1.20
	1.275	2.25	2.30
E-44 (Equil. S=1.225) (Init. W=51.65 g)	1.10	0.05	0.05
	1.14	1.12	0.98
	1.18	2.12	2.45
	1.20	3.12	3.75

* Equilibrium sulphur is calculated by using $H_2S/H_2 = 0.00220$ and taking $K_1 = 0.00256$. After the silicon addition, E is computed by using $0.00256 = K'_1/f_s$ where f_s is the activity coefficient of sulphur. Plotting f_s vs pct S by using the four equilibrium runs in ref. 1, it is found that $f_s = 1.72$, from which $E = 0.50$ pct S whereas a short extrapolation of their curve in Fig. 1 gives a value closer to 0.51 pct S. The choice of $E = 0.51$ would shift the calculated curve in Fig. 1 slightly to the right near the equilibrium sulphur and would make the agreement perfect.

** The weight used in each interval is the previous weight minus 2 g of sample, e.g., $W = 59.35$ from 0.08 to 2.56 hr, and 57.35 from 2.56 to 3.75 hr, etc.

† The mean value between the experimental curves for E-39 and E-44 near equilibrium. See Fig. 1.

‡ The values plotted but not tabulated in ref. 1. These, as well as the initial weights, were kindly furnished by J. P. Morris, whose cooperation is gratefully acknowledged.

Run E-39 was made under $H_2S/H_2 = 0.00310$, therefore the reported values of sulphur are corrected to $H_2S/H_2 = 0.00304$ as pointed out by the investigators.

Fig. 2—Reaction rate at 1600°C. $H_2O/H_2 = 0.0182$, data of Gokcen and Chipman.

The earlier investigation of Chipman and Li³ on reaction 1 was later superseded by those of Sherman, Elvander, and Chipman,⁴ Sherman and Chipman,⁵ and Chipman and Sherman,⁶ who used 175 g of metallic charge and passed a mixture of $H_2 + H_2S$ over the melt at a rate of 500 ml per min.⁴ Table II gives the results of calculations by using in Eq. 7, their values for L , W and K' , for each heat in which the only varying dissolved element was sulphur.

In the experimental results of Sherman et al., the initial charge of sulphur, and the time used to obtain equilibrium were not given. It was mentioned, however, that after the melt had been at constant temperature for 1 hr, the first sample was taken and at hourly intervals the metal was sampled and analyzed until the three successive samples yielded identical results and then the melt was "... considered ..." at equilibrium without further proof. The three successive hourly samples limit a period of 2 hr when θ is taken as zero for the first sample. The accuracy of sulphur analysis in their experiments was not given explicitly but it may safely be assumed as ± 0.005 pct whereas Morris and Williams reported that their duplicate samples usually checked within 0.01 pct. Accordingly, an actual change of 0.01 pct S in metal may not be indicated by the three samples which appear to yield identical results when the dissolved sulphur is a substantially lower fraction of the equilibrium value as shown in the last column of Table II. Further, in view of the similarity of apparatus used in these and other investigations,^{8,9} it will be shown later in this paper that the calculated minimum time should be multiplied by a factor of two to three in order to obtain a closer magnitude of their actual experimental time. This is quite likely the result of less intimate contact of the gas with metal than that obtained by the bubbling technique. The gas mixture in their experiments was directed over the metal through a preheater tube located at a certain distance above the surface of the melt and, therefore, a part of the gas must have escaped without reaching to and reacting with metal. (See Fig. 1 or ref. 4 for the arrangement of apparatus and compare with Fig. 2 of ref. 9.) Consequently, the experimental results of Sherman et al. are seriously questionable especially in the range of sulphur below 1 pct.

Eqs. 4 to 7 can be modified to make similar calcu-

lations on the experiments of Rosenqvist and Cox. The calculations show that the required time could have been decreased proportionally by increasing the rate of gas circulation which was of the order of 60 ml per min in their experiments.

Equilibrium in reaction 2 was recently studied by Dastur and Chipman.⁸ The average rate of hydrogen flow was 260 ml per min, the weight of metal 70 g, and the equilibrium constant $K_2 = H_2O/H_2 \cdot O\% = 3.93$ at 1600°C in their investigation. The charge, consisting of electrolytic iron, contained initially $X_0 = 0.080$ pct O as reported by the manufacturer, and the equilibrium heats less than 0.140 pct. The deviation in their oxygen analyses was usually 0.0006 pct, and occasionally 0.0020. These data cannot be used directly in equations similar to 4 and 7, because in this case L varies substantially with time as $L = 0.260 + W 22.4 dX/100 \times 16 dt$. Thus Eqs. 4 and 6 assume the following forms for reaction 2:

$$\text{Available } H_2O \text{ in} \\ \text{liters per min} = 0.260 K_2 E - L K_2 X \quad [4a]$$

$$\frac{16}{22.4} \left[0.260 K_2 E - K_2 X \left(0.260 + 0.98 \frac{dX}{dt} \right) \right] = 0.70 \frac{dX}{dt} \quad [6a]$$

Integration and rearrangement of Eq. 6a gives:

$$(1 + K_2 E) \log \frac{E - X_0}{E - X} + \frac{K_2}{2.3} (X_0 - X) = \frac{16 \times 0.260 \times 100 \times K_2}{2.3 \times 22.4 \times W} t = 0.453t \quad [8]^*$$

* Eq. 7 is a special form of 8 in view of the fact that $K'_1 \cdot E$ and $K'_1 (X_0 - X)/2.3$ are very small for reaction 1 and may be omitted with an error of less than 1 pct.

Eq. 8 gives the minimum time of 4.8 min for the variation in oxygen content from 0.080 to 0.138 when E is taken as 0.140. If 33 pct of the available oxygen was transferred experimentally into the melt as will be shown later, then 14.6 min should be sufficient to establish equilibrium in this reaction. This is in good agreement with their experimental result showing that the equilibrium was established within approximately 15 min.

The application of the preceding equations to the rate studies of Gokcen and Chipman⁹ in reaction 3 is not so simple due to the considerable variation of $K'_3 = (H_2O/H_2)^2 Si\%$ with silicon content and the simultaneous change in oxygen concentration. The variation in dissolved oxygen, however, is small above 0.30 pct Si and it can be estimated from Fig. 2, or calculated by using $[Si\%][O\%]^2 = 2.8 \times 10^{-5}$; the latter gives a total variation of only 0.0004 pct O for a gain of 0.10 pct Si from 0.45 to 0.55, hence, the effect of $d[O\%]/dt$ on the available rate of H_2O is negligibly small in this range. Therefore, equations similar to 4, 5, and 6 may be used to calculate the minimum time for the gain of 0.10 pct Si from 0.45 to 0.55 pct. From their data, $W = 35$ g, $L = 0.260$ liter per min; from a short extrapolation of the lower curve for silicon in Fig. 2, it is found that $E = 0.62$ pct from which $K'_3 = 2.05 \times 10^{-4}$ at equilibrium, and at the average silicon value of 0.50, $K'_3 = 2.12 \times 10^{-4}$. The latter value of K'_3 is found graphically from a curve passing through $\log 2.05 \times 10^{-4}$ and 0.62 pct Si, and parallel to the curve of $\log K'_3$ vs pct Si for the equilibrium runs with fully preheated gas mixtures. The choice of K'_3 in this man-

Table II. Minimum Time Required for the Gain of Sulphur Toward Equilibrium in the Experiments of Sherman Et Al.

Run No.	$K' \times 10^3$	E	Sulphur, Pct**		Minimum Time, Hr, θ^\dagger	Equivalent Time, Morris et al. [‡]	S Pct = x' When Gain = 0.01 Pct S Per 2 Hr	$x' - 100$ Pct E
			Initial X_0	Final X				
S-23*	2.02	4.21	4.00	4.04	4.33	0.64	4.104	97.5
M-1	2.18	2.11	1.985	2.025	7.27	1.07	2.011	95.3
M-4	2.27	1.25	1.16	1.20	10.5	1.54	1.155	92.4
M-17	2.20	0.67	0.603	0.643	17.0	2.50	0.572	85.4
M-27	1.976	0.42	0.363	0.403	25.2	3.71	0.312	74.3
M-36	1.56	0.25	0.20	0.24	42.0	6.18	0.114	45.6
F-3	2.835	0.312 ^{††}	0.259	0.299	20.7	3.04	0.235	75.3

* Runs S-23 and F-3 are from refs. 4 and 6 respectively; others are from ref. 5.

** X/E 100 pct = 96 pct and $X - X_0 = 0.04$ pct S. The substitution of these values in Eq. 7 gives $\log(1 + 1/E) = 10.64K'\theta$. X_0/E 100 pct is 90, 86, and 80 pct for runs M-17, M-27, and M-36, respectively.

† For X/E 100 pct = 96 pct and $X - X_0 = 0.08$ pct S, the time required for the heats of M series is 12.5, 17.2, 25.7, 36.2, and 57.5 hr, respectively.

†† The highest sulphur reported in ref. 6. (See also ref. 5.)

‡ Calculated by using the data in cols. 2 to 4 and the experimental conditions of Morris et al.^{1,2} θ of Sherman et al. divided by θ of Morris et al. equals approximately 6.8 for the same E , X , and X_0 values.

ner, for the runs in reaction rates, is due to the existence of thermal diffusion as the result of insufficient preheating of the entrant gas as pointed out by the investigators. The equation for the maximum rate of silicon gain is then:

$$\frac{d[\text{Si}\%]}{dt} = \left(\sqrt{\frac{2.12 \times 10^{-4}}{\text{Si}\%}} - 0.0182 \right) \frac{0.260 \times 14}{0.35 \times 22.4} \quad [9]$$

The calculation from the integrated form of this equation shows that the increase of silicon from 0.45 to 0.55 should require 1.58 hr, whereas the experimental time is 4.8 hr. The effective fraction of the available oxygen is then 1.58/4.8 or 33 pct, which increases somewhat with increasing silicon. The graphical solution is obtained by determining at 0.50 pct of average silicon, (a) the slope $d[\text{Si}\%]/dt$ from Fig. 2, and (b) the maximum slope $d[\text{Si}\%]/dt$ directly from Eq. 9; the ratio of (a) to (b) is the effective fraction which is 32 to 36 pct depending upon the graphical accuracy of the slope.

Conclusions

Eq. 6 shows explicitly that for a given reaction, W should be small, L large, and X_0 as close to E as possible in order to decrease the time required for the attainment of a final concentration near the equilibrium value. In a series of similar reactions, with the same values of W , L , X_0/E , and X/E , approach to equilibrium is faster for higher values of K (cf. reactions 1 and 2).

It may be pointed out that Eq. 6 is sufficiently accurate for most purposes involving high temperature investigations. The exact form is:

$$\frac{dX}{dt} = AK(a_x - a_x) \quad [10]$$

where A is the combined constants for a reaction of the type 1 or 2 together with the experimental conditions, K is the true equilibrium constant, and a the activity based upon percent concentration, i.e., $a_x = f_x \cdot X$. Substitution of the activity coefficients in Eq. 11 as:

$$\frac{dX}{dt} = \frac{AK'_E}{f_E} (f_E \cdot E - f_x \cdot X) = AK'_E \left(E - \frac{f_x}{f_E} X \right) \quad [11]$$

shows that Eqs. 6 and 11 are identical when f_x/f_E is unity, which is very nearly the case when the initial value of $E - X$ is small. In exceptional cases, such

as in reaction 2, $K'_2 = K_2$, hence f_x/f_E is unity. Experimental results are seldom accurate enough to give a ratio of f_x/f_E as a function of X for the integration of Eq. 11. A comprehensive use and discussion of this equation will be in a forthcoming paper together with new data.

The reactions above are being studied by using a cascade-type platinum wound furnace, and by following the technique of Morris and coworkers with some improvements in view of the foregoing considerations regarding the reaction rates.

Summary

The equation $\log \frac{E - X_0}{E - X} = \frac{62.1 \times L}{W} K'_1$ is de-

rived to relate the time required (t) to the change of percentage of sulphur in liquid iron from (X_0) towards (X) in the direction of the equilibrium sulphur (E) in the reaction:

The constants L and W represent the hydrogen flow rate and the weight of metal respectively.

Similar equations are derived for the reactions:

Available data and experimental methods are analyzed, interpreted, and critically evaluated by using the derived equations.

Lattice Parameter of Beta Titanium at Room Temperature

by B. W. Levinger

THE lattice parameter of the β form of pure titanium has been measured at elevated temperature.^{1,2} No attempt was made, however, to correct the parameter obtained to room temperature.

In the course of phase diagram studies at Armour Research Foundation and elsewhere, the variation of β -phase lattice parameter with composition has been established in a number of binary and ternary systems involving titanium. It was possible to extrapolate in these instances to 100 pct Ti to find the apparent lattice parameter of β titanium at room temperature. Table I lists the results thus obtained. The suggested value for the lattice parameter of β titanium is the average of the extrapolated values 3.276 ± 0.003 kX. This suggested value gives an interatomic distance in β titanium of 2.837 kX and

Table I. Apparent Lattice Parameter of Beta Titanium at Room Temperature

System	Extrapolated β Phase Parameter (kX)	Limit of Stable β Phase Wt Pct Ti	Reference
Ti-V	3.275	85	4
Ti-Cr	3.28	85	6
Ti-Mo	3.278	94	7
Ti-Nb	3.276	90	8
Ti-Fe	3.278	64	8
Ti-Mo-Cr	3.275	96	9 Fig. 1
Ti-Mo-Mn	3.277		9 Fig. 2
			9 Fig. 3

for α titanium in a similar range.⁵ It was thus possible to calculate the parameter at 900°C. The value of 3.305 kX agrees well with 3.3065 given by Eppelsheimer.²

The majority of values reported in the literature^{1-4, 8} were given as Angstroms. In at least one case, ref. 8, it was shown that they actually represented kX units. The source of this confusion appears to be that a large number of tables of X-ray emission spectra list wavelengths as Angstroms and give values in kX units. The accepted conversion factor for kX

hence a Goldschmidt atomic diameter (coordination number 12) of 2.925 kX. The latter agrees closely with the value of 2.93 given by Hume-Rothery.³

From the data of Adenstedt and coworkers⁴ it was possible to determine by extrapolation the mean coefficient of linear expansion for β titanium in the range from room temperature to 1000°C. This value, 10.1×10^{-6} per degree C, compares with about 11×10^{-6}

High Temperature Modification of TiCr_2

by B. W. Levinger

THE system Ti-Cr has been studied by several investigators.¹⁻⁴ Though titanium and chromium are completely miscible at high temperatures, an intermediate phase of the approximate atomic proportions TiCr_2 has been identified at various compositions between 60 and 68 wt pct Cr. The structure of this phase was established as the cubic C15 (MgCu_2) type with 24 atoms per unit cell and a lattice parameter 6.929 kX.²

During a study of the ternary system, Ti-Mo-Cr,⁵ the existence of a high temperature modification of the TiCr_2 phase was discovered. In a series of alloys annealed at 1300°C and containing from 60 to 70 wt pct Cr and 5 pct Mo, a new phase was present which did not correspond to either β solid solution or TiCr_2 . By trial, the new phase was identified to be of the hexagonal C14 (MgZn_2) structure with 12 atoms per unit cell. Further work showed that the hexagonal structure was, in fact, also present in binary Ti-Cr alloys quenched from high temperatures.

To make the identification more certain, the intensities of the various reflections were calculated assuming a composition TiCr_2 and C14 structure. Table I lists reflection planes, interplanar distances, calculated intensities, and a comparison of these values with the lines of a binary Ti-Cr alloy (66 pct Cr) annealed for 20 min at 1385°C and water quenched. Since high angle lines were more diffuse, the correspondence between visually observed and calculated intensities was not as good at these angles.

Lattice parameters were computed to be $a = 4.922$ kX, $c = 7.945$, $c/a = 1.614$. The corresponding interatomic distances are: titanium to titanium distance, 3.00, kX, chromium to chromium distance, 2.43, kX, titanium to chromium distance, 2.88, kX. These compare to 3.00, 2.45, and 2.87 kX in the cubic phase, respectively.²

The atomic positions in the C14 structure are as follows:

Titanium $1/3, 2/3, z; 1/3, 2/3, \frac{1}{2}-z;$
 $2/3, 1/3, \bar{z}; 2/3, 1/3, (\frac{1}{2}-\bar{z});$

Chromium $0, 0, 0; 0, 0, \frac{1}{2};$
 $\frac{2x}{x}, \frac{x}{x}, \frac{1}{4}; \frac{2x}{x}, \frac{x}{x}, \frac{3}{4};$
 $\frac{x}{x}, \frac{2x}{x}, \frac{1}{4}; x, 2x, \frac{3}{4};$
 $\frac{x}{x}, x, \frac{1}{4}; x, x, \frac{3}{4};$

The values of x and z were calculated for the alloy mentioned and found as follows: $z = 0.061, x = 0.165$. The values assumed in the intensity calculations were those for an ideal close-packed lattice or $z = 1/16, x = 1/6$.

Work in the Ti-Mo-Cr system indicates that γ_2 , the hexagonal modification of TiCr_2 , is the stable phase above 1300°C, while γ_1 with the cubic structure is stable below 1000°C. X-ray examination of a number of alloys annealed at intermediate temperatures showed that the hexagonal and cubic phases can coexist. Alloys quenched from 1000°C and annealed at 1100° and 1200°C showed small

Arc-Furnace Equipment and Its Operation

At the Kennecott Utah Refinery

by H. A. Shaw and H. G. G. Whitton

This paper describes the use of the electric-arc furnace for the production of tough-pitch, horizontal cast copper shapes and the production of copper anodes from tank house anode scrap. This installation is the only one of its kind in the United States.

SINCE the initial use of electric-arc furnaces for refined copper melting on a commercial scale at Copper Cliff in 1936, this type of melting has been of extreme interest to everyone in any way connected with copper casting and fabricating. Early in 1948, Kennecott Copper Corp. decided to build an electrolytic copper refinery at Garfield, Utah. One of the major decisions to be made at that time was the type of furnace to be used for melting cathodes for casting into refined copper shapes and for melting anode scrap for the production of anodes. Based on the results obtained from arc furnaces by the International Nickel Co. of Canada, at Copper Cliff, and by the American Smelting and Refining Co., at Baltimore, coupled with certain important economic factors such as having an adequate amount of relatively cheap power available at the Magna Central Power Plant, high cost of poles and oil in the Salt Lake District, and the lack of natural gas at that time, the final decision was to install electric-arc furnaces rather than the standard type of reverberatory furnaces.

Experience has shown certain parts of the original installation to have been inadequate or in need of modification. Although the present status of arc-furnace melting at the Utah Refinery is far from perfect, nevertheless substantial progress has been made.

At the Utah refinery, copper is melted in three 15-ft diam, size "M" Lectromelt furnaces, two of

which are used for melting cathodes and one for remelting anode scrap.

Each furnace is energized from a 13,800-225 v, 3-phase, 60-cycle, 6000-kva (at 40°C rise) oil-immersed water-cooled transformer. Auxiliary equipment for each refined copper furnace includes a charging machine, launders, ladle, 40 ft diam Walker-type casting wheel, bosh, and inspection conveyor. The anode furnace differs in that it is charged by hand from an elevated platform and the anodes are picked off the 24-ft diam casting wheel by a takeoff hoist and loaded directly into specially designed trailers, Figs. 1 and 2.

Electrical Equipment

Electric power to operate the arc furnaces is generated at the Kennecott-owned Magna Central Power Station two miles distant and transmitted to the Refinery outdoor substation at 44,000 v. At this point it is stepped down to 13,800 v and carried through concrete-lined underground tunnels to the switchgear and then to the primary side of the furnace transformers. The power is conducted from the Y-connected secondary bus bars of the transformer to the electrode arms by means of 22 flexible copper cable conductors per phase. Each cable has a cross-sectional area of 1,750,000 circular mils, giving a total area of 38,500,000 circular mils per phase. The power is carried from these cables to the three individual electrode holders by means of water-cooled copper bus tubing. The electrode clamps are incorporated in the electrode holders and are released by air pressure working against a spring in the clamp control cylinder.

The movement of the electrode arms is either automatic or manual. The automatic control is used during melting and is regulated by three Westing-

Fig. 1—Diagrammatic layout of furnaces and casting equipment.

house Rototrols which actuate the electrode arm winch motors. The manual control is used whenever it is necessary to raise one or all the electrode arms, such as prior to shutting off the power, or slipping electrodes. The low voltage connections in the transformer provide 13 taps ranging from 85 to 225 v. Suitable connections may be made to a motor operated tap changer which allow the operator to use any one of four selected voltages. Present settings give a selection of 120, 147, 173, or 190 v phase to phase. Most melting is done using 173 v.

A rheostat on each phase provides a limited control of the current for each tap setting.

Data compiled during the two years of operation indicate that 245 kw-hr of power are required to melt one ton of copper.

Description of Furnaces

The three arc furnaces are identical in construction. The walls are fabricated of $1\frac{1}{8}$ in. steel plate, cylindrical in form, having an inside diameter of 15 ft 0 in., and provided with four openings, namely,

Fig. 2—General view showing the two refined copper melting furnaces and auxiliary casting equipment in the foreground. The anode copper melting furnace and casting equipment is in the background.

charge slot, skim bay, taphole, and a small inspection hole near the taphole. The charge slot is located at the rear of the furnace diametrically opposite the furnace taphole. The skim bay is on the side opposite the masts, 45° from the charge slot. The furnace bottom is also made of $1\frac{1}{2}$ in. steel plate formed on a 14 ft 2 in. spherical radius. For pouring the furnaces are hydraulically tilted about an axis in line with the furnace taphole spout.

The holding capacity of the furnaces when new is approximately 50 tons. The wear on the bottom refractories resulting from operations increases this quantity to about 65 tons before relining of the bottom is necessary.

Furnace Refractory Construction

The furnace lining consists of a refractory cement pad 1 to 8 in. thick formed on the bottom of the empty shell to develop the desired radius for the construction of the superimposed brick bottom. This is followed by two courses of $2\frac{1}{2}$ in. brick keys laid to conform to the desired spherical radius. The third course is constructed from 9 in. special shape, chemically bonded magnesite brick, and the fourth and final course is built from $13\frac{1}{2}$ in. special shape, chemically bonded magnesite brick. The main section of the side walls is built from $9\times 6\times 3$ in. No. 1 keys laid up as headers and backed up by two $4\frac{1}{2}$ in. courses of fireclay brick. An anti-surge ledge projects 9 in. at the metal line. Special precautions are taken to allow vertical expansion to take place without exerting pressure on the roof brick. An annular space between the bottom brick and the sides of the steel shell is allowed. This space is filled either with insulation brick or powdered magnesite to permit expansion of the bottom. Expansion is also provided in the side walls above the metal line by the use of $\frac{1}{8}$ in. corrugated paper between each brick, Fig. 3.

Only basic brick will withstand the corrosive action of the furnace atmosphere due to the concentration of copper oxide fume at high temperature. This fume will react rapidly with silica brick, high alumina brick, and to a lesser extent with refractories of a sillimanite or mullite composition. Silicon carbide brick will withstand the action of the fumes but rapidly breaks down to a silica slag in the presence of oxygen at elevated temperatures that are at times unavoidable.

As low refractory costs and avoidance of operational shutdowns are two of the major objectives of arc-furnace melting, it is necessary that every detail of furnace construction be carefully engineered and that the refractories be selected with due regard to previous results. The actual taphole consists of a 4 in. ID carbofrax tube set in place with magnesite cement in a slot left during the construction of the wall. Accurate location of this tube is important because it determines the level of the molten copper in the furnace, acts as a skimmer, and because it must be positioned so that the furnace can be drained completely. When casting must be interrupted it is only necessary to tilt the furnace back 5° onto safety blocks. This allows the molten copper to drain from the inclined taphole tube. It is possible to hold a furnace full of molten copper in this position for an indefinite period by intermittent application of power.

Arc-Furnace Roof Construction

Roofs are constructed with basic brick using $9\times 4\frac{1}{2}\times 3$ in. series of brick plus some special shapes. When building a roof, the fabricated steel roof support ring is located accurately about a permanent cement template, the surface of which is a dome having a spherical radius of 17 ft 4 in. Wooden templates are set by dowels so that the electrode and vent openings will be located accurately in the finished roof. The roof is developed by constructing a series of brick rings using side arch and wedges to follow the shape of the cement template. Rings of specially shaped, adapter brick are used as needed. The electrode and vent openings are made by using special side arch wedge shapes that form a slightly conical opening with the larger diameter up so that the brick rings are held in position by a definite taper. Circumferential expansion is allowed by the use of a $\frac{1}{8}$ in. corrugated cardboard spacer every eighth brick. At the present time no cement is used in laying the brick. However, after the roof has been installed on the furnace and the temperature raised, the outside surface of the roof is grouted with a thin slurry of magnesite cement to seal the openings between adjacent brick, Fig. 4.

The desirability of roof insulation is being investigated and its use will depend upon results obtained from current experiments.

Since the melting practice requires definite control of the furnace atmosphere, it is necessary that

Fig. 3—Section of arc furnace showing arrangement of refractory lining. Diagrammatic section of roof shows section through vent, electrode opening and main portion of roof.

Fig. 4—Arc furnace roof for 18 in. diameter electrodes, showing water-cooled vent plate and water-cooled banjo-type damper.

a gas-tight seal be provided around the electrodes, otherwise "bottlenecking" of the electrode will occur and gas will escape from the furnace. Individual water-cooled glands are used on each electrode. These glands are suspended several inches above the furnace roof. A flat ring of fireclay key brick is set on the roof around each electrode opening so that the small end of the brick comes in contact with the graphite electrode, thus protecting the lower face of the water-cooled electrode gland from copper splash. With a new cold roof, a space of 2 in. is allowed between the lower face of the gland and the fireclay brick pad. This allows the roof to rise due to the expansion of the brick while being brought up to operating temperature, without subjecting the roof to the additional weight of the glands. This opening is sealed by forming a slip joint using a soldier course of fireclay side arch brick strapped to the gland and projecting down so as to come in contact with the fireclay base. The weight of the water-cooled gland is carried from the operating platform by projecting lugs from each gland. These are electrically insulated from the steelwork of the platform by fireclay brick. The glands now in service are fabricated from $\frac{3}{8}$ in. boiler plate. The roof vent opening is built from

Fig. 5—Refractory lining in refined copper arc furnace showing new brick bottom, anti-surge ledge and water-cooled, boiler plate charge slot.

9x6x3 in. side arch wedge brick to form a slightly conical opening 13 in. in diameter. A water-cooled base plate, constructed from $\frac{3}{4}$ in. boiler plate and containing a 13 in. diam opening, is cantilevered over the vent in such a manner as to allow the weight of the water-cooled section to be carried by the steel roof ring without interfering with the expansion of the roof.

Charge Slot Construction

The original construction of the wirebar furnace charge slot followed previous practice which consisted of a water-cooled copper casting bolted to the outside shell of the furnace and having a minimum opening 44 in. wide x $4\frac{1}{2}$ in. high. The original anode furnace charge slot was similar in design to the standard, copper, water-cooled charge slot casting, but was fabricated from $\frac{3}{4}$ in. boiler plate. The minimum opening was 59 in. wide x 6 in. high, making it possible to charge anode scrap or rejected, full sized anodes. On the outside, a steel door operated by an air cylinder was installed. The refractory portion of the chute consisted of a sill built from special shapes of silicon carbide designed to give a slope of 30° . Trouble was experienced from the start with this construction. The silicon carbide sill brick had a very short life, the extreme heat seriously warped the steel door, and the continual spray of molten metal rapidly formed an objectionable build up of copper skulls on the refractory adjacent to the water-cooled opening of the slot. It was felt that these troubles must be associated with the use of higher arc voltages inherently necessary with 60 cycle power, as such troubles were not encountered on a similar installation using lower voltage and 25 cycle power. As will be discussed later, it was also felt that the 14 in. diam electrodes being used were too small.

It then became necessary to develop a new charge slot construction to meet these conditions. After exhausting the practicabilities of various refractories it was decided to investigate the possibility of using a water-cooled boiler plate slot. In April 1951, a water-cooled boiler plate sill was installed and results were very promising. Development of the idea was continued until at the present time each furnace is equipped with a complete water-cooled charge slot consisting of the sill, two side sections, and a top section. As a safety measure the charge slots have been raised approximately 10 in. to avoid the possibility of the water-cooled section coming in contact with molten copper when the furnace is set back on the low blocks at such times when it may be necessary to stop casting, Fig. 5.

Electrodes

The original furnace installation utilized 14 in. diam graphite electrodes. Shortly after operations started it was realized that the 14 in. diam electrodes would not give the desired melting rate. In spite of every effort it was not possible to obtain melting rates above 15 tons per hour. To obtain this value it was necessary to operate on the higher voltage positions which in turn caused the furnace walls and roof to overheat dangerously to the point of destruction. In an effort to correct this a change was made to 18 in. diam electrodes.

At the time it was reasoned that the larger diameter electrodes would tend to shield the arc to the extent that the sidewalls would not overheat as much, thus making it possible to operate for longer

periods of time on the higher voltage positions. It was also thought that the percentage of down time due to broken electrodes would be decreased because of the greater mechanical strength of the larger electrodes. Experience has proved this reasoning to be correct. Results of the change from 14 to 18 in. diam electrodes are summarized as follows: 1—Melting rate was increased from 15 to 22 tons per hour. 2—Lower wall temperatures enabled the furnace to operate on higher voltages without too much danger of overheating. 3—Less electrode breakage resulted in a decrease in electrode consumption from 5.0 to 4.2 lb per ton. 4—Power factor decrease from 0.7 to 0.6 resulted in greater load on transformer. 5—Stability of the arc at the same current value decreased.

Efforts made to increase the power factor at the furnace by changing the current, voltage, or reactance have not proved successful. While it has been possible to increase the power factor by lowering the current, this has in turn given rise to in-

Fig. 6—Anode take-off hoist and cooling sprays used to cool anodes and remove scale after anodes are placed in anode rack cars.

creased arc instability. Likewise, raising the voltage beyond 173 v, phase to phase, gives rise to overheating and instability.

Anode Copper Furnace

As previously mentioned the construction of the anode furnace is identical to the two refined copper furnaces except for a wider charge slot. In contrast to the refined copper furnaces, the anode furnace is hand charged from an elevated platform.

As in the refined furnaces the copper flows from the furnace taphole down the launder into the pouring ladle and is then cast into one of the 12 molds on the 24 ft diam casting wheel. After cooling, the tops of the anodes are raised approximately 2 in. by push-up pins so that the take-off hoist can pick them up and hang them, properly spaced on an anode trailer. Adequate water cooling is provided by overhead sprays through which the loaded trailer is moved so that the anodes will be cooled and some of the scale removed by quenching before they are delivered to the tank house, Fig. 6.

Launders, Ladle, and Wheel

Molten copper from the cathode melting furnace flows from the furnace taphole into launders arranged so that it is possible to cast into either or

Fig. 7—Arc furnace showing fume recovery system.

both of the two wheel positions. The copper flows from the launders directly into a pouring ladle and then is cast into one of the 17 molds on the 40 ft diam Walker-type casting wheel. The casting wheel revolves continuously with the wire bars being dumped into a water bosh located diametrically opposite the ladle position. After dumping, the molds are automatically righted and then hand sprayed with a slurry of bone ash and water. The refined shapes fall on a steel conveyor in the bosh where they are cooled and then elevated to a second conveyor for inspection and loading.

The original plant construction included a vertical-type, low frequency induction furnace unit at each casting wheel, so arranged that the molten copper could flow down the launder from the arc-furnace taphole and enter the induction furnace through a 5 ft refractory tube set in the hollow trunnion about which the induction furnace was rotated.

Starting February 4, 1951 experiments were conducted in casting molten copper direct from the arc-furnace launder into the pouring ladle. It was found that by close pyrometer control of casting temperature, rate of charging, and condition of the copper at the taphole that casting conditions could be

Fig. 9—Charging machine illustrating method of charging cathodes and reject wirebars into the arc furnaces.

maintained more uniformly and casting delays almost entirely avoided with the elimination of the induction units.

Fume Recovery System

The fume recovery system is divided into two parts: one is used to collect the fume oxide from the anode furnace and the other is used to collect the fume oxide from the two refined copper furnaces. This is to keep the anode fume, which must be re-treated to remove the impurities and precious metal values, separate from the relatively pure copper oxide dust recovered from the refined copper furnaces.

The fume that escapes through the roof vent contains from 5 to 6 lb of cuprous oxide for each ton of copper melted. The charge slot skim door and vent are adequately hooded and are connected to a central fume pipe, Fig. 7. The fume is forced through a type N, Roto-Clone collector, the exhaust gases pass through a 25 in. diam stainless steel stack 45 ft high. The slurry containing the copper oxide dust is pumped through a 36 in. filter press, Fig. 8.

Charging

As no refining is accomplished in the usual operation of the arc furnace, every effort is made to insure that the cathodes used for melting are free from nodulation, have a fine grained structure, and are washed to completely remove electrolyte. Special attention is given to washing electrolyte from the pockets formed by the cathode loops. The washed cathodes are stacked directly from the tank house washing machine on to rubber-tired, four wheel, steered trailers. Each trailer carries two piles of cathodes having a total average weight of 15,000 lb. After weighing, the stacks of cathodes are removed from the trailers by use of fork lift trucks and stored in an area directly behind the arc furnaces. Each of the two refined copper furnaces has an independent charging machine, consisting of a structural steel framework which supports a carriage containing two hydraulic tilting magazines, Fig. 9. Each magazine is designed to take a full pile of cathodes. The carriage is operated electrically so that when a charged magazine is lined up with the furnace charge chute a pair of hydraulically operated rams enables the operator to push the slightly inclined cathodes into the charge chute at any desired rate. The charging rate is determined by the furnaceman who takes into consideration the casting rate de-

sired, the pouring temperature, and the average weight of the cathodes being charged. The furnaceman sets the desired charging rate on the dial of a flexopulse, this causes a light to flash at the charging operators stand each time a cathode should be charged. In the meantime a pile of cathodes is being lifted and placed into the empty magazine of the charging machine by means of a 10-ton, overhead crane. As soon as the companion magazine is empty, the carriage is moved over allowing the newly filled magazine to come into charging position.

Cathodes from the charging machine slide down an inclined chute, through the water-cooled charge slot, directly into the bath of molten metal. Reject wirebars are charged back into the furnace by means of a chute that extends from the operating platform of the cathode charging machine to the charge slot.

Furnace Operation

The furnace operating crew consists of a furnaceman for each operating furnace, two chargers for each wirebar furnace, and three chargers for the anode furnace. One overhead craneman services the charging aisle and the crane follower hooks up the charge material for each operating furnace and records the necessary information regarding amount of material charged.

The set and oxygen content of the cast shapes is controlled by regulating the flow of gas and fume through the 13 in. diam water-cooled vent in the roof. A banjo shaped water-cooled boiler plate damper is used to regulate the vent opening. When the vent is closed the reducing action of the volatilized carbon from the electrode arc and the volatilized copper from the superheated copper at the point of arc impingement causes rapid reduction of the oxygen content of the molten copper. When the vent is opened the scavenging action of air which enters at the charge slot removes these elements and allows the molten copper to pick up oxygen. Control of the set of the cast copper shapes is maintained by careful regulation of the vent opening. Spot optical oxygen determinations are made every half-hour on samples taken at the furnace taphole along with block samples taken at the point where the molten copper flows from the furnace taphole into the launder leading to the pouring ladle. In normal operation the furnace is held in a horizontal position, the molten copper flowing from the furnace due to displacement by the incoming cathodes. The tilting mechanism enables the operator to tilt the furnace forward 45° when it is necessary to drain it, or tilt it backward 5° when skimming or during holdovers.

In all arc furnaces used for melting copper the arc strikes on a comparatively bare bath of molten metal. Melting under this condition results in a characteristic wave motion in the molten metal which in turn gives rise to excessive short circuit current surges. Meter readings become wild, sidewall temperatures rise, melting rate decreases and the furnace transformer tends to overheat. To overcome this characteristic a refractory ledge has been built at the metal line and extending in toward the center of the furnace approximately 9 in. This, however, is only a partial cure and it is necessary to cause a refractory slag ledge or shelf to build up and extend in still further to act as a damper to the wave motion. Since there are normally no slag making constituents available in the furnace, except ash from the consumed electrode, it is necessary

to cover part of the bath with magnesite material containing the desired amount of lime and silica. The arc fuses this material to a viscous condition and as the fluid or semifluid slag is formed the action of the arc showers it on to the walls of the furnace. Eventually it flows down the side of the wall and strikes the refractory ledge and extends in over the bath of molten metal, and as the metal temperature is lower than the wall temperature a ledge of slag develops around the metal line of the furnace except at the charge slot and skim bay sections. It has been observed that the melting rate of the furnace increases up to a certain point, as the ledge increases. Any of the brick that spalls from the walls or roof eventually causes the bank or ledge to grow until at times the build up may extend beyond an electrode. An opening may or may not develop which will allow the arc flame to come in contact with the molten bath. In such cases it is necessary to stop casting, open up the skim bay door and break off and remove the excess portion of ledge.

The amount of regular skimming necessary is entirely dependent upon the amount of refractory material that accumulates and is mostly caused by refractory failure. Under normal conditions the so-called slag consists of porous lumps of material, impregnated with small masses of copper. Ideal melting conditions are usually possible only after a good shelf has formed and the surface of the bath partly covered by the so-called slag. It is of extreme importance that the bath should not be allowed to become fully covered so that arcing will occur on the covering of the bath. If this happens a new set of conditions then immediately develops, the meters become stabilized, there is no surging in the low tension leads, the usual crackling noise that is an indication that copper melting is progressing in a satisfactory manner ceases and is replaced by a strong characteristic hum. At the same time copious fumes of volatilized carbon issue from the vent in the roof, and wall and shell temperatures rise at an exceedingly high rate, which in a very short time can

cause destruction of the roof and wall above the metal line. Simultaneously the copper temperature will drop due to the insulating covering on the bath. If the operator attempts to raise the metal temperature by increasing the power input then destruction of the furnace will progress at a still more rapid rate. Under these conditions the copper rapidly becomes oxygen free and is then fouled by the presence of undesirable elements. It will be observed when this happens that the molten copper flowing from the taphole no longer has a bright metallic appearance, but is soon covered by a dull flaky scum.

During the charge slot cleaning operation, also when slipping and adding electrodes, it is of course necessary to shut off the arc power and tilt the furnace forward to provide molten copper for the continuation of casting. Due to these delays an actual furnace melting rate of 22 tons per hour will only result in a continued casting rate of 19 to 20 tons per hour. Tercod pouring lips on the casting ladles enable casting to be continued 24 hr a day for as long as four days, without a shut down. Upon the completion of the tonnage requirements for a certain cast shape, the copper is diverted to the appropriate launder and casting is commenced on the alternate wheel which has previously been loaded with molds for casting the desired shape.

At the present time only horizontal shapes of electrocopper are cast at the Kennecott Utah Refinery, however, the melting equipment is ideal for the production of all types of vertical cast electro and deoxidized shapes if these should be required at some future date.

Technical Note

Effect of Carbon on the Volume Fractions and Lattice Parameters Of Retained Austenite and Martensite

by C. S. Roberts

THE advent of a sensitive X-ray method of analysis recently has allowed the determination of retained austenite in amounts as low as 0.3 pct.¹ As a result this phase has been found in quenched low carbon steels where its presence has not been generally suspected.

In the course of a study of the tempering process,²

C. S. ROBERTS, Junior Member AIME, is associated with Metallurgical Laboratories, The Dow Chemical Co., Midland, Mich. TN 142E. Manuscript, Sept. 29, 1952.

retained austenite determinations were made by the X-ray method on a series of high purity Fe-C alloys and plain carbon steels. The chemical analyses of these materials and details of the hardening procedure are given in Table I. Results were obtained after quenching to 72°F (22°C) and -321°F (-196°C). Austenitizing temperatures were between 100° and 150°F above A_s or A_{cm} . All proeutectoid cementite or ferrite was in solution. The combination of the results with those of Averbach, Castleman, and Cohen,¹ and earlier results of Esser

Fig. 1—Effect of carbon content on retained austenite content after quenching to room temperature.

and Bungardt³ are shown in Figs. 1 and 2. The results are better-defined functions of carbon content than have been available previously. The variation is smooth and there is no significant difference between the behavior of the high purity alloys and the plain carbon steels.

Also necessary for this work was a collection of all known data showing the effect of carbon content

Fig. 2—Effect of carbon content on retained austenite after refrigeration to -321°F (-196°C).

on the austenite and martensite lattice parameters. All of the results which could be found⁴⁻¹² are shown in Fig. 3. The data of Kurdjumov and Kaminsky are apparently low. Neglecting their points, the parameters in kX units may be expressed by the function: Martensite: $c = 2.861 + 0.116x$; $a = 2.861 - 0.013x$; $c/a = 1.000 + 0.045x$; and austenite: $a = 3.548 + 0.044x$; $x = \text{wt pct C}$.

Effect of Tensile Strain at Low Temperatures on Deformation Twinning in Ingot Iron

by Glenn W. Geil and Nesbit L. Carwile

A metallographic study was made of deformation twinning (Neumann lamellae) in ingot iron slowly deformed in tension at -196° and -150°C . The results showed that twinning is initiated mainly during the initial stages of plastic deformation. However, the breadth of the twins generally increases with increase in strain up to fracture of the specimen.

THE results of an investigation of the effect of low temperatures on the flow, fracture, strain hardening, and strain aging characteristics, and the true stress-strain relationship for specimens of ingot iron deformed in tension were reported recently.^{1,2} In that study specimens of ingot iron, in different initial conditions, were slowly deformed in tension at various temperatures between -196° and $+100^{\circ}\text{C}$. A phenomenon observed, but only briefly reported, was the formation of deformation twins (Neumann lamellae) in the specimens deformed at the lower temperatures. Preliminary metallographic examination of these specimens indicated that there was apparently some correlation between the deformation twinning and the strain of the specimen and that this factor merited further investigation.

Some recent investigations have indicated a direct association of Neumann lamellae and the fracture of the metal. Bruckner^{3,4} postulated that the twinning immediately precedes the fracture and the latter is initiated by the stopping of the propagation of twins, either at subgrain boundaries or at other structural features. Tipper and Sullivan⁵ postulated that Neumann lamellae are initiated by the shock or a shock wave set up at fracture in the still highly stressed unbroken metal, and that a high rate of deformation is a necessary condition for their formation.

An extensive metallographic examination, therefore, was made of many of the specimens used in the study of ingot iron at this Bureau and of additional specimens deformed to selected strains under various conditions. The present paper summarizes the effects of deformation under these conditions

upon the breadth and scope of the deformation twins. Other features of twinning will be discussed in another paper.

Material and Testing Procedure

All of the specimens were prepared from one lot of ingot iron, as hot-rolled, of chemical composition other than iron as follows: C, 0.02 pct; Mn, 0.02; P, 0.005; S, 0.018; Si, 0.002; Cu, 0.10; O, 0.058; and N, 0.002.

Cylindrical tensile specimens with a 2 in. gage length were used. The reduced section was slightly tapered from each end; the diameter (0.438 in.) at the midsection of the gage length was about 0.003 in. less than at the ends. The specimens were finished to the final dimensions by grinding and polishing in the axial direction. The ends of the specimens were machined with $\frac{3}{4}$ in. x 10 threads and the shoulder fillets were machined to a radius of 0.75 in.

The specimens were extended slowly in tension (deformation rate less than 0.5 pct reduction in area per minute) while immersed in an appropriate cryogenic liquid maintained at the desired temperature. The minimum diameter of the specimen was measured during the test by means of a specially designed reduction of area gage accurate to 0.0001 in.⁶ A detailed description of the testing equipment and the method of maintaining the desired temperature is given in a previous paper.¹

Each specimen, after deformation to a specified strain at a selected temperature, was sectioned longitudinally and examined metallographically. The preparation of specimens for metallographic examination was carried out in the usual manner by mechanical polishing and etching.

Results and Discussion

Deformation twins in specimens of ingot iron extended slowly in tension at -196° and -150°C are shown by the representative micrographs of Figs. 1

G. W. GEIL, Member AIME, and N. L. CARWILE are Metallurgists, National Bureau of Standards, Washington, D. C.

Discussion on this paper, TP 3483E, may be sent, 2 copies, to AIME by April 1, 1953. Manuscript, Sept. 12, 1952; revised, Nov. 26, 1952. Los Angeles Meeting, February 1953.

the lower yield point, 0.045, Figs. 1c and d and 2a. However, no significant increase in the number of twins per unit area was observed as the specimens were further deformed to greater strains even up to fracture, Fig. 2b, c, and d. Furthermore, specimens extended at -150°C to selected strains revealed this same general dependency of deformation twinning on the plastic strain. A very few twins were observed in the specimen extended to the upper

yield point (total true strain of 0.0037) and the number of twins per unit area generally increased with increase in the strain of the specimens up to a total true strain of about 0.06. Further deformation of specimens up to fracture did not significantly increase the number of twins.

The values of strains corresponding to the upper and lower yields, respectively, were smaller in the specimens extended at -150° than at -196°C . The

amount of twinning at the upper or lower yield, respectively, was also smaller at -150° than at -196°C . However, the dependency of the number of deformation twins on the degree of strain ($\log_e A_0/A$) was similar at each test temperature. Thus, the deformation twinning apparently occurs with small strains irrespective of the yield-point phenomenon.

The results definitely show that the twinning in hot-rolled ingot iron slowly deformed in tension at

low temperatures is initiated during the early plastic deformation. Furthermore, there was no evidence obtained that indicated any increase in the number of twins per unit area in the deformed specimens as a result of fracture. The number of twins per unit area in the fractured specimens was not significantly greater than that in specimens extended to a strain of about 0.06 or more but not fractured. Therefore, a shock or shock wave set up at complete fracture

is not an essential requirement for the formation of deformation twins in ingot iron at low temperatures.

The micrographs of Figs. 3 to 6, which were taken at high magnification and with oblique lighting, show the effect of strain on the breadth of twins. All of the twins observed in specimens deformed to small strains were relatively narrow (Figs. 3b and 5a) whereas the majority of twins in specimens deformed to greater strains were somewhat broader, although some narrow twins were observed in these latter specimens. Apparently an increase in strain tends to cause a growth in breadth of a twin; however, it is recognized that the observed breadth is also dependent upon the relative orientation of the twin plane to the plane of the section observed.

The thinner twins observed in the same micrograph or even in the same grain with broader twins may be due to a less favorable orientation of the twin plane with respect to that of the parent grain and the direction of loading of the specimen. Examination of a very large number of micrographs revealed that: 1—Twins in the same direction within a grain are, in most cases, approximately the same breadth, and 2—The breadth and irregularity in shape of twins generally increase with increase in the strain up to the fracture of the specimen.

The severe deformation of the ferrite grains in the necked section of the specimen extended to fracture at -150°C (Fig. 6b and c) resulted in a general obscuring and considerable bending of the deformation twins. The bending was caused by deformation of the grains subsequent to the formation of the twins. Bent twins also were observed in other specimens deformed at -150° and -196°C . The ductility of the twins as revealed by degree of bending in tension at low temperatures indicates that deformation twinning is not the cause of low temperature embrittlement of ingot iron.

The data obtained in this study, such as that shown in Figs. 3 to 6 illustrating the growth of deformation twins in ingot iron and in many other micrographs not shown, indicate that the twinning may be a nucleation and growth process and not a simultaneous shear mechanism as often proposed. However, for brevity of the present paper, discussion of these fea-

tures is not included but will be given in detail in a separate paper.

Conclusions

The results of a metallographic study of deformation twinning in specimens of hot-rolled ingot iron slowly extended in tension at -150° and -196°C to selected strains show that twinning is initiated during the early stages of plastic deformation and that a shock or shock wave set up at fracture is not an essential condition for their formation. The number of twins per unit area increases with increase in strain up to a true strain of about 0.05 or 0.06, but greater strains do not appreciably increase the number of twins. The breadth and irregularity in shape of the twins generally increase with increase in the strain up to fracture of the specimen.

The ductility of deformation twins as revealed by the degree of bending in tension at low temperatures indicates that deformation twinning is not the cause of low temperature embrittlement of ingot iron.

Technical Note

Slip and Grain Boundary Sliding as Affected by Grain Size

by Nicholas J. Grant, Italo S. Servi, and Arup Chaudhuri

IN a recent paper by Servi and Grant,¹ it was illustrated that the slip band spacing and stress based on creep test data were related by the equation:

$$d \cong \frac{1}{\sigma}$$

where d is the spacing in millimeters and σ is the stress in psi, based on a more complete equation proposed by Orowan. It was shown further,¹ that for a given grain size, the slip band spacing became larger with decreasing stress (and was independent of temperature), until such time that the slip band spacing becomes greater than about one-half the grain diam-

eter. When this occurred, the mechanism of deformation in creep of 2S aluminum at high temperature changed from slip to grain boundary deformation (sliding). Additional metallographic evidence is now available which confirms this in a most interesting fashion.

Fig. 1—2S aluminum tested in creep at 900°F, 880 psi, 3.5 pct total elongation. Oblique illumination. Shows slip bands in coarse grain and grain boundary sliding in fine grained zones. Stress in vertical direction. X150. Area reduced approximately 50 pct for reproduction.

Fig. 2—2S aluminum tested in creep at 900°F, 880 psi, 9 pct total elongation. Oblique illumination. Coarse grain shows slip, fine grains show grain boundary sliding, and medium sized grain (upper center) shows both. Stress in vertical direction. X150. Area reduced approximately 50 pct for reproduction.

Fig. 3—2S aluminum tested in creep at 900°F, 880 psi, 9 pct total elongation. Micrograph near necked zone. Shows slip and grain boundary sliding in medium grains and slip in coarse grain. Stress in vertical direction. X150. Area reduced approximately 50 pct for reproduction.

Fig. 4—High purity magnesium tested in creep at 500°F, 670 psi. Shows pyramidal slip of two coarse spacing to be accommodated by fine grain which shows grain boundary sliding instead. Stress in vertical direction. X50. Area reduced approximately 50 pct for reproduction.

The 2S aluminum was recrystallized in a double treatment to yield a mixed grain size. A test bar, similar to that described in ref. 1, was heated at 950°F for 3 hr, producing a rather regular, fine grain size. A second heat treatment of 1150°F for 1 hr then yielded a mixed grain size of such nature that in some parts of the specimen small grains were imbedded in a larger grain, see Fig. 1.

These specimens were tested in creep at 900°F at a stress of 880 psi. Fig. 1, after 3.5 pct elongation, shows that the large crystal deformed by slip. The fine grains located in the large grain do not show slip bands, however, the grain boundaries are "thickened" indicating grain boundary sliding. The lower left slip band is apparently continuous on either side of the fine grained cluster, but does not penetrate these fine grains. The slip band spacing is obviously much larger than the grain diameter.

Fig. 2, after 9 pct deformation, shows slip as the deformation mechanism of the coarse grain and grain boundary sliding as the mechanism of the fine grained cluster in the upper right corner. In the upper center is a grain which is apparently of marginal size since a slip band has developed in it.

Fig. 3 shows another specimen deformed more than 9 pct (near the necked area). Here the slip band spacing is small enough so that many of the finer grains are more than twice the average slip band spacing. These grains also deformed by slip, the spacing being almost the same as that of the coarse grain. At the bottom is a cluster of very fine grains, the larger ones showing one or two slip bands, while the finer ones show some grain boundary sliding.

Similarly, a high purity magnesium specimen, Fig. 4, tested at 500°F and 670 psi when tested in creep shows pyramidal slip bands of uniform spacing in a large grain but no slip bands in the small enclosed grain, the grain boundary of which shows evidence of sliding.

These micrographs clearly support the evidence that grain boundaries have a blocking effect on slip at high temperatures; and at a given grain size, for a given stress, will undergo sliding as a primary mechanism of deformation.

Absolute Rate Theory Applied To Rate of Growth of Pearlite

by J. H. Frye, Jr., E. E. Stansbury, and D. L. McElroy

The rates of growth of pearlite in high-purity Fe-C alloys have been measured as a function of the transformation temperature. These and other data have been correlated in terms of a derived rate equation. Activation energies for the growth were found to be 24,200 cal per mol of austenite for the 0.78 pct C alloy and 27,600 cal per mol for the 0.93 pct C alloy. Theoretical implications are discussed.

AN excellent review of the the theoretical and experimental studies on the mechanism and kinetics of the eutectoid reaction has been presented recently by Mehl and Dube.¹ They have pointed out that these investigations have followed two lines of approach: 1—experimental studies and derivations of expressions for the overall transformation characteristics, and 2—derivation of expressions for the nucleation and growth rates in terms of fundamental

processes. Investigations of the latter type have been concerned for the most part with the nature of the growth at the austenite-pearlite interface in plain carbon and alloy eutectoid steels. They discuss two theories of the rate of growth of pearlite from austenite—those of Brandt and of Zener. Both derive rate equations which are based on the assumption that carbon diffusion is the controlling mechanism. Mehl and Dube,¹ Zener,² and Brandt^{3, 4} have attempted to calculate growth rates by use of these equations together with thermodynamic and diffusion data. The results are encouraging, but agreement is not so good as to constitute verification of the theories.

Furthermore, it is not clear how these equations are to be used to study the effect of alloying elements which apparently exert little influence on carbon diffusion, but markedly decrease growth rates. It is not clear whether or not the addition to iron of an alloying element which does not diffuse during transformation can alter the rate of growth of body-centered from face-centered cubic iron. That it can greatly decrease the overall transformation rate has

STANSBURY, Junior Member AIME, is Professor of Metallurgy, University of Tennessee, Knoxville, Tenn., and D. L. McELROY is Graduate Student, Metallurgical Engineering, University of Alabama and Oak Ridge Institute of Nuclear Studies Graduate Fellow.

Discussion on this paper, TP 3489E, may be sent, 2 copies, to AIME by April 1, 1953. Manuscript, May 23, 1952; revised, Sept. 30, 1952. Los Angeles Meeting, February 1953.

This paper is based on research at the Metallurgy Div., ORNL by D. L. McElroy, to be incorporated in a thesis to be submitted in partial fulfillment of the requirements for the degree of Master of Science in Metallurgical Engineering to the University of Alabama.

Fig. 1—Growth rate data at 708°C.

been shown by Austin and Pierce,⁵ who investigated a binary Fe-Cr alloy containing 9 pct Cr (carbon less than 0.03 pct). In this alloy, the two-phase region extends over a temperature interval of 5°C. There is no reason to believe that chromium diffuses during transformation below this region. The maximum rate of isothermal reaction occurs at 700°C, with a time for 50 pct transformation of 180 sec. In a high-purity Fe-C alloy containing 0.93 pct C, this time is only 1.3 sec at a temperature of 547°C.⁶ In pure iron, the time is presumably much less. It is possible that the effect of chromium in slowing the transformation rate is entirely in its influence on rate of nucleation and that rate of growth is quite unchanged, but there does not appear to be any reason to suppose that this is the case.

From an examination of the growing eutectoid interface, it is evident that diffusional processes are essential to the growth mechanism; however, it is not evident that diffusion, per se, is the controlling mechanism of the several which must operate across the interface during growth. In the growth of pearlite from austenite, carbon must diffuse in the austenite from the ferrite to the cementite interface. Furthermore, some diffusion of iron must occur to accommodate the volume changes accompanying the formation of ferrite and cementite. In addition, the actual interface mechanisms whereby austenite of the correct carbon content is transformed to cementite and to ferrite must be considered. Unfortunately, little is known of the latter for phase transformations of any type; but it does not seem improbable that they could constitute the rate-determining step in the growth process. Of the many

mechanisms that might be considered, the following are given as examples: 1—atom by atom jumps across the interface, 2—formation of groups of atoms of the proper composition which, by suitable rearrangement, pass from the initial to final phase, 3—shears of either large or small numbers of atoms at the interface, and 4—growth by movement of dislocations. Each of these should operate with a characteristic activation energy.

It appears that additional work in this field is needed and also that a more general approach to the problem might be profitable. Such an approach is the following:

1—Derive a general equation for the rate of growth of pearlite from austenite which assumes no particular mechanism except that the rate is determined by the surmounting of an energy barrier.

2—Measure the rate of growth of pearlite from austenite in a high-purity Fe-C eutectoid, interlamellar spacings, and the necessary thermodynamic quantities to calculate free energy differences between pearlite and austenite. Use these thermodynamic and rate data to calculate the constants in the equation.

3—Measure rates of growth, interlamellar spacings, and thermodynamic quantities for Fe-C eutectoids which contain a third element, and use these data to calculate the constants in the equation.

4—Observe the effect of the alloy additions on the constants of the equation. This should lead to some understanding of the effect of alloying elements on rate of growth.

In this paper, an equation is derived which expresses rate of growth of pearlite from austenite in high-purity Fe-C alloys as a function of the difference in free energy between the two, the activation energy for the reaction, the absolute temperature, and certain constants. Constants in this equation, including the activation energy, are calculated from the following experimental data: 1—heat of transformation and specific heats for the Fe-C system, and 2—rates of growth of pearlite at various degrees of super cooling.

Heats of transformation⁷ and specific heat⁸ data have been taken from the published values for such quantities. Data on the rate of growth of pearlite in a 0.93 pct C high-purity steel have been taken from the work of Hull, Colton, and Mehl.⁶ Growth-rate data on a high-purity steel containing 0.78 pct C have been determined experimentally in this investigation.

Results of measurements of the growth rate of a high-purity, 1 pct Mn eutectoid steel with a similar analysis of the data will be reported in a later paper. It is hoped that these studies will contribute to a better understanding of the effects of alloying elements in steel and of the factors governing hardenability.

Experimental Procedure

The objectives of the experimental work reported herein were to obtain further data on the growth rate of the pearlite-austenite interface in eutectoid Fe-C alloys of sufficient purity to make theoretical interpretations of the data as straightforward as possible. Hull, Colton, and Mehl⁶ have reported the pearlite growth rates for a high-purity Fe-C alloy containing 0.93 pct C. Since such an alloy is slightly hypereutectoid, it was desired to obtain data on an alloy as near 0.80 pct C as possible.

High-purity electrolytic iron previously reduced with hydrogen was melted with high-purity graph-

Table I. Analyses of High-Purity Steels

Steel	C	Si	Mn	P	S	Cr	Ni
0.78 pct C*	0.78	0.03	0.005	0.003	0.013		
0.93 pct C	0.93	0.002	0.004	0.005	0.0001	0.005	0.006

ite in fused zirconia crucibles using induction heating and a purified argon atmosphere. The melt was solidified in the crucible to give an ingot 1¼ in. in diameter and 4 in. long. The ingot was homogenized for 48 hr at 1100°C in vacuum after which it was hot rolled to ½-in. round rod. The analysis of the resulting material is given in Table I, along with the analysis of steel used by Hull, Colton, and Mehl.⁹

The rod was then machined to 7/16-in. diam to remove possibilities of any extraneous effects due to a contaminated surface, and then cut into disks 0.060 ± 0.003 in. thick for transformation studies.

The experimental method of running the isothermal transformations and determining the growth rates was essentially that of Hull, Colton, and Mehl.⁹ It consists of heating the specimen into the austenite range and quenching to a predetermined isothermal subcritical temperature after which it is quenched to room temperature. The transformation is observed to occur by a process of nucleation at the grain boundaries and the subsequent growth of the pearlite as nodules. These nodules are roughly spherical at the higher temperature (20°C subcool), growing from both sides of the boundary from which they are nucleated, and may consume several grains before impinging on other nodules. At lower temperatures, growth is hemispherical from nuclei on one side of the grain boundary, and the relatively greater rate of nucleation prevents growth much greater than the grain radius before impingement occurs.

The rates of growth at the higher temperatures were obtained by examining a large number of nodules and plotting the diameter of the largest nodule as a function of the time. At lower temperatures, the measurements are more difficult, since the growth is hemispherical. In this case, it is necessary to restrict measurements to those grains which are known to have been cut near their center, thus permitting measurements on the nodule perpendicular to the grain surface. A problem encountered in such measurements is the location of the grain boundary when nucleation has occurred with subsequent growth on both sides of the grain boundary. A technique of repeated polishing and etching, followed by examination under polarized light, was developed which revealed the martensite grain boundaries so that their extension through the pearlite could be accurately predicted. The growth rates were obtained from the slope of the maximum nodule-time plots.

Hull, Colton, and Mehl⁹ have reported a half-reaction time for their steel of 2 sec at 599°C for material having ASTM grain size No. 1. Since impingement occurs after 15 pct transformation to an extent making growth measurements impossible, it is evident the accurate growth-rate data are difficult to obtain for specimens undergoing such rapid transformation. In this investigation, an austenitizing temperature of 1300°C for 30 min was used to increase the grain size to No. -1. Under these conditions, the shortest half-reaction time was increased to about 3 sec, thus permitting improved accuracy of measurement.

All transformations were carried out automatically in equipment developed for these studies. The apparatus consists essentially of a small platinum-wound furnace, a stirred lead bath, and mercury quench arranged so that the specimen mounted on the end of a piston rod and activated by pressure-vacuum could be automatically indexed to any posi-

Fig. 2—Growth rate data at 640°C.

tion. The entire space above these three units and in which the specimen moves is filled with purified argon. In this manner, a very clean lead bath is maintained which, with the bright specimens, gives excellent quenching conditions. The transfer time for one position to another is approximately 0.2 sec, and transformation times are probably consistent to about 0.05 sec. The time of transformation is taken as the time interval from quenching into the lead bath to quenching into the mercury. The austenitizing temperature was controlled to ± 5°C and the lead-bath to ± 0.3°C. The lead-bath temperatures are measured with chromel-alumel thermocouples standardized against Bureau of Standards Metals.

Representative plots of nodule radius vs time are shown in Figs. 1 and 2. At the lower temperatures, both a nodular and a feathery constituent are observed. The appearance of the nodular structure was identical with the fine pearlitic structures measured at slightly higher temperatures. No measurements were made on the feathery constituent, but were confined to the nodular constituent.

The growth-rate data for the 0.78 pct C steel are summarized in Fig. 3. The data of Hull, Colton, and Mehl⁹ on a steel containing 0.93 pct C are indicated for comparative purposes. It is evident that the rates are slightly slower for the eutectoid steel and that a definite maximum in the growth rate at a critical degree of undercooling is obtained whereas no maximum appears for the other steel.

A maximum in the rate curve has not been previously reported for the growth of pearlite. Recent electron microscope studies⁹ have shown that pearlite can coexist with bainite as low as 450°C. In the present investigation, growth-rate data at the lower temperatures were taken only on the characteristic hemispherical pearlite regions of the structure.

Theory

It is customary to attempt to describe data on reactions in solids by means of exponential-type rate equations. The usual approach in applying absolute rate theory is to establish a mechanism and compute the constants in these equations, the validity of the resulting equation being established by comparison of calculated and experimental rate data. In our present state of knowledge of rate processes in

Fig. 3—Summarized growth rate data.

solids, it does not seem possible to carry out these calculations. Therefore, the procedure is followed of deriving an equation which is of the correct form and then of calculating its constants from rate data. Usually, an exponent is calculated, and this is taken to be the activation energy. This procedure may lead to false physical meaning being attached to constants which are merely empirical. This danger is inherent in the use of any of the present rate equations. Nevertheless, it is to be hoped that through such efforts a fuller understanding will eventually be attained of rate processes in solids.

An attempt will now be made to derive a general equation for the rate of growth of pearlite from austenite. This equation will be used in the present paper to calculate the activation energy for this reaction in the Fe-C alloys considered here. Finally, it is hoped that it will be useful in studying the effect of third elements on this rate of growth.

The mechanism of growth of the austenite-pearlite interface is assumed capable of treatment by the Eyring rate theory.¹⁰ With this assumption, it has been found that the Eyring rate equation in the form which takes into account a forward and backward reaction is applicable; i.e.,

$$n = \frac{mkT}{h} \left(\exp \frac{-\Delta F^* +}{RT} - \exp \frac{-\Delta F^* -}{RT} \right) \quad [1]$$

where: n is the net rate of movement of activated complexes; m , the transmission coefficient; k , Boltzmann's constant; h , Planck's constant; R , the gas constant; T , the absolute temperature; $\Delta F^* + = F^* - F_a$; $\Delta F^* - = F^* - F_p$; F^* = the free energy of the activated complex; F_a = the free energy of the austenite; and F_p = the free energy of the pearlite.

In the present application, the transmission coefficient, m , will be assumed to be constant. The linear rate of growth, r , of the pearlite-austenite interface is considered as being proportional to n , the

net rate of movement of activated complexes. Account must also be taken of the fact that the pearlite spacing decreases with decreasing temperature of formation. The work of Pellissier, Hawkes, and Mehl¹¹ has shown that it is difficult to arrive at an exact relationship between interlamellar spacing and temperature of formation. This is due to the difficulty of securing sufficiently precise data. Their published data for plain carbon eutectoids can be correlated linearly, to a rough first approximation, with the number of degrees of supercooling at which the pearlite formed. Furthermore, Roberts and Mehl¹² have shown that the rate of growth of austenite from pearlite is inversely proportional to the number of degrees of supercooling at which the pearlite was formed. It will, therefore, be assumed that the rate of growth of pearlite from austenite is inversely proportional to the number of degrees of supercooling at which the reaction takes place.

Consideration of the above leads to

$$r = cT\Delta T \left(\exp \frac{-\Delta F^* +}{RT} - \exp \frac{-\Delta F^* -}{RT} \right) \quad [2]$$

Where

$$c = \text{constant} \quad [3]$$

This may be rewritten

$$r = cT\Delta T \exp \frac{-\Delta F^*}{RT} \left(1 - \exp \frac{\Delta F}{RT} \right) \quad [4]$$

where $\Delta F = F_a - F_p$

If ΔF is taken as the difference in free energy between austenite and pearlite per mol† and its value

† A mol of pearlite or austenite is defined as 6.023×10^{23} atoms of iron plus carbon.

calculated from the expression derived in the appendix, then for all temperatures within the pearlite range, ΔF is sufficiently small compared to RT to permit close approximation of $\exp(\Delta F/RT)$ by the first term of its series expansion.

Thus,

$$r = cT\Delta T \exp \frac{-\Delta F^*}{RT} \left(1 - 1 + \frac{\Delta F}{RT} - \frac{(\Delta F)^2}{2!RT^2} + \dots \right) \quad [5]$$

or

$$r = C' \Delta T \Delta F \exp \frac{-\Delta F^*}{RT} \quad [6]$$

where C' is a constant.

This constant, C' , must include, among other things, the number of atoms in the activated complex. If the complex contains several atoms, the approximation will be badly in error.

The activation energy, ΔE^* , and the activation entropy, ΔS^* , may be introduced through their relation to the activation-free energy. Thus, neglecting pressure-volume effects,¹³

$$\Delta F^* = \Delta E^* - T\Delta S^* \quad [7]$$

Then the rate of growth will be given by

$$r = C' \Delta T \Delta F \exp \frac{-\Delta E^*}{RT} \exp \frac{\Delta S^*}{R} \quad [8]$$

Finally,

$$r = C \Delta T \Delta F \exp \frac{-\Delta E^*}{RT} \quad [9]$$

where C is a constant.

The relation may be rewritten in the form

$$\ln \frac{\Delta T \Delta F}{r} = -\ln C + \frac{\Delta E^*}{R} \cdot \frac{1}{T} \quad [10]$$

If the derived relation is correct, a semilogarithmic plot of $\Delta F \Delta T / r$ against $(1/T)$ should yield a straight line.

Values of r and T resulting from experimental studies on the 0.78 pct C carried out in this investigation—along with computed values of $10^3/T$, $(\Delta F \Delta T / r)$, and r —have been listed in Table II. Similar values for the high-purity alloy of 0.93 pct C investigated by Hull, Colton, and Mehl⁶ are shown in Table III. The values of ΔF have been obtained from the expression in the appendix by graphical integration.

Fig. 4 shows a plot of $\log (\Delta F \Delta T / r)$ vs $1/T$ for each of these steels. It is evident that a reasonably straight line results in each case. The equations for these two steels are:

0.78 pct C,

$$r = 2.86 \Delta F \Delta T \exp (-24,200/RT) \quad [11]$$

0.93 pct C,

$$r = 31.6 \Delta F \Delta T \exp (-27,600/RT) \quad [12]$$

Discussion

The uncertainties involved in any application of rate equations to solids have been pointed out earlier. For purposes of this discussion, however, it will be assumed that the numerators of the exponents in Eqs. 11 and 12 are activation energies.

From the slopes of the plots in Fig. 4, an activation energy of 24,200 cal per mol of austenite is obtained for the 0.78 pct C alloy and 27,600 cal per mol for the 0.93 pct C alloy. It is evident that the values of these two activation energies are almost within the scatter of the data; and, for this reason, only limited significance may be attached to their relative values. The data for the 0.78 pct C alloy, however, distinctly lie above those of the 0.93 pct C alloy, resulting in a lower value for the constant, C , for the lower carbon alloy. Mehl¹² and coworkers have shown that the interlamellar spacing of hypereutectoid steels is finer at the same ΔT , and this should contribute to faster rates as indicated earlier. Unfortunately, it is impossible without actual measurements of interlamellar spacing to estimate possible changes in the activation entropy.

Activation energies for diffusion of carbon in austenite have been determined.¹⁴ They vary from approximately 36,000 cal for a carbon concentration of 0.22 pct to approximately 28,500 cal for 1.35 pct C. Activation energies found here are low, being 24,200 cal for 0.78 pct C and 27,600 cal for 0.93 pct C. It may be that activation energies for diffusion along the interface are lower than in the austenite used in the diffusion experiments. Thus, these results are not inconsistent with the theory that rate of growth is controlled by diffusion of carbon.

Fig. 4—Plot of $\frac{\Delta F \Delta T}{r}$ vs $\frac{1}{T}$ showing correlation of data according to Eq. 10.

On the other hand, the activation energy for the self-diffusion of γ iron has been reported¹⁵ as approximately 70,000 cal per mol; and it does not seem probable that this would be reduced to the values obtained in the present case by reason of the influence of the stresses or other factors at the interface. Whether the activation energies reported from the present analysis are representative of some interface mechanism of the type previously discussed cannot be stated with data now available. Additional experiments designed to give information on the individual processes are necessary.

Eq. 10 is of approximately the same form as Eq. 11 of Zener's paper,² which was derived on the assumption that the rate of growth is determined by diffusion of carbon. The slight difference is that Zener assumes that the free energy varies linearly with ΔT ; whereas, in the present paper, a more accurate variation with temperature is given. The presentation of this derivation is believed to be desirable for two reasons:

1—Zener has shown that his equation is of correct form to describe the rate of growth of pearlite from austenite, and this implies that the rate is determined by carbon diffusion, since this is the basis of Zener's derivation. It is important to point out that the same equation can be arrived at without any assumption as to the actual mechanism of the reaction beyond the idea that it is controlled by the crossing of an energy barrier.

2—An equation which is not based on a particular mechanism is needed as a guide for the study of the effect of alloying elements on the rate of growth. For example, in work now in progress at these laboratories, it has been found that manganese, which decelerates the growth of pearlite from austenite, does not appreciably partition between cementite and ferrite below a certain isothermal transformation temperature. These results are in general agreement with data reported by Hultgren¹⁶ for a manganese steel. The observation that the degree of partitioning is a function of the isothermal transformation temperature further complicates a theoretical treatment of the kinetics of the austenite-pearlite

transformation, for it is now necessary to obtain thermodynamic data on transformations to non-equilibrium products. Thermodynamic and interlamellar spacing measurements are now being made in the hope of analyzing the influence of manganese on rate of growth, in terms of its effect on ΔF , ΔE^* , and possibly ΔS^* .[‡] It is hoped that this work can be

† Qualitatively, it is clear that additions of manganese will decrease the temperature at which the free energy of nonpartitioned pearlite is equal to that of austenite. This follows from the fact that phase diagram work has shown that manganese decreases this temperature for partitioned pearlite and from the fact that the free energy of partitioned pearlite must be higher than that of nonpartitioned. This will result in a smaller ΔF at a given temperature for the transformation to nonpartitioned manganese pearlite than for the transformation to binary pearlites at a given temperature, unless the effect of manganese on heats of transformation and specific heats outweighs the effect on temperature. Furthermore, it seems probable that manganese will increase interlamellar spacing.¹¹ These two effects will tend to result in a lower rate of growth of pearlite from austenite. A quantitative valuation must await the results of work now underway in these laboratories.

extended to a study of the effect of manganese on growth of α iron from γ iron in a binary Fe-Mn alloy. This would be particularly enlightening, since isothermal growth on supercooling should occur without any diffusion of any kind. Again, the influence of manganese would be analyzed in terms of its effect on ΔF , ΔE^* , and possibly ΔS^* .

Conclusions

The rates of growth of pearlite from austenite in two high-purity steels may be represented by the following equations:

$$\text{For 0.78 pct C steel,} \\ r = 2.86 \Delta F \Delta T \exp -24,200/RT$$

$$\text{For 0.93 pct C steel,} \\ r = 31.6 \Delta F \Delta T \exp -27,600/RT$$

As predicted by the theory, data for the steel containing 0.78 pct C show a maximum in the curve of growth rate vs temperature.

Appendix

The free energy of the austenite-to-pearlite reaction can be calculated by means of the following equation:

$$\Delta F = \Delta E (T_i - T)/T_i - \int_{T_i}^T dT' \int_{T_i}^{T'} \Delta C dT''/T'' \quad [13]$$

where: ΔF is the free energy of austenite minus that of pearlite per mol; T_i , the absolute temperature of the transformation at equilibrium; T , the absolute temperature of a given transformation; ΔC , the difference in heat capacity between austenite and pearlite, calories per mol per degree; and ΔE , the internal energy per mol of austenite minus that of pearlite at equilibrium temperature.

A careful search of the literature has failed to yield a reliable value of the heat of the eutectoid transformation, ΔE . Epstein¹⁷ lists values from 875 to 1170 cal per mol of austenite. Analysis of the data of Awbery and Snow⁷ indicates a value of approximately 1000 cal per mol. A value may be estimated from the enthalpy data of pure iron by Darken and Smith,⁸ from the heat of formation of cementite given by Darken and Gurry,¹⁸ and the heat of solution of graphite in austenite by Smith.¹⁹ Considering the transformation as the decomposition of pearlite into ferrite and graphite followed by the transformation of α to γ iron and the subsequent solution of graphite in the γ iron to form austenite gives a value of approximately 1050 cal per mol. Preliminary direct measurements of the heat of transformation by calorimetric methods in these laboratories has indicated that this value is about correct.

The heat capacity of steel below the temperature of transformation appears to be insensitive to large changes in carbon content and small changes in other elements.⁷ In view of this, values of heat capacity of pure α and γ iron have been taken from the work of Darken and Smith.⁸ The last term of the above equation has been integrated graphically. The heat of transformation has been taken as 1050 cal per mol and the equilibrium temperature of transformation as 723°C; the computed values of ΔF are given in Table IV.

Titanium-Manganese System

by D. J. Maykuth, H. R. Ogden, and R. I. Jaffee

A phase diagram for alloys containing from 0 to 66.9 pct Mn was determined. Two compounds, tentatively labeled δ and γ , were found in this range. The δ compound is located at about 66.9 pct Mn and melts congruently at 1330°C. The γ compound has a composition near 53 pct Mn and originates in a peritectic reaction at 1200°C between liquid and δ . β and γ enter into a eutectic reaction at 1175°C. The β phase field terminates in a very sluggish eutectoid reaction between α and γ at 550°C.

MANGANESE is one of the important alloying addition elements to titanium. As a β -stabilizing addition for α - β and β alloys, it provides high strength with adequate ductility.¹ Two of the earliest commercial alloys contain manganese as a major alloying component.²

The earliest published data on the constitution of Ti-Mn alloys was that of Wallbaum,³ who reported the existence of the compound TiMn_2 . The transformation range of commercial-purity Ti-Mn alloys was investigated by Craighead, Simmons, and Eastwood¹ who found limited α solubility and a lowering of the β transus to about 790°C at 7 pct Mn. Preliminary work by the authors of this paper, using high-purity titanium, confirmed the β -stabilizing action of manganese and showed the existence of several intermediate phases in the Ti-Mn system.⁴ More recently, McQuillan⁵ determined the β transus temperatures for high-purity Ti-base alloys containing up through 4.4 pct Mn. These data are given in Fig. 1.

The present investigation covered alloys made with a high-purity base. The constitution of titanium-rich alloys made with commercial titanium has been reported^{4,6} by Holladay, Kura, and Jackson.

The alloy range covered in the present investigation was from 0 to 69.5 pct Mn. This alloy range extends slightly beyond the composition of the first congruent-melting compound encountered on proceeding from the titanium end of the system. A description of the materials and methods used in the determination of the diagram is given in the Appendix.

The partial phase diagram determined for the Ti-Mn system is shown in Fig. 2. Details on equilibria in the titanium-rich alloys are given in Fig. 3.

Liquid-Solid Relationships

Observations on the cast structures of the arc-melted ingots showed that the terminal solid solution of manganese in β titanium enters into a eutectic reaction with an intermetallic compound labeled γ . As will be shown later, this compound has a composition around 53 pct Mn. The eutectic reaction

Fig. 1—The β transus curve for titanium-rich manganese alloys as determined by McQuillan.⁵

temperature was determined as 1175°C by thermal analysis which also showed that the γ phase originates in a peritectic reaction at 1200°C. Fig. 4 shows typical eutectic structures for alloy compositions on both sides of the eutectic composition which is located at 42.5 pct Mn.

In alloys over the range of 45.4 through 69.5 pct Mn, a second intermetallic compound, labeled δ , was identified as the primary phase. This phase consistently increased in amount as the manganese content approached 66.9 pct, and, as shown in Fig. 5, an alloy structure containing 66.9 pct Mn consisted essentially of the δ compound. Thermal-analysis data indicate a melting point of about 1330°C for the δ intermediate phase. At 67.0 pct Mn, small quantities of a new, higher manganese-content phase were observed in the form of Chinese-script eutectic particles. Comparison of Fig. 6a and b shows an increasing quantity of this phase as the composition was increased to 69.5 pct Mn.

The formation of peritectic γ in arc-melted alloys containing 45.4 pct Mn and above appears to be almost entirely suppressed, as shown in Fig. 7a and b. This is because of the narrow freezing range available for its formation by peritectic reaction and because of the very high cooling rates obtained in

D. J. MAYKUTH is Research Metallurgist, H. R. OGDEN, Junior Member AIME, is Assistant Supervisor, and R. I. JAFFEE, Member AIME, is Supervisor, Nonferrous Physical Metallurgy Div., Battelle Memorial Institute, Columbus, Ohio.

Fig. 2—Partial phase diagram for iodide titanium-manganese alloys.

freezing after arc melting. In fact, these arc-melted alloy structures appear as a "eutectic" series between the β and δ phases.

In an attempt to complete the peritectic reaction, an alloy containing 53.6 pct Mn was melted in graphite and slowly cooled through the solidification range at a rate of about 1°C per min. As illustrated in Fig. 8, this structure clearly shows the peritectic rings of γ around primary δ . Despite this slow rate of cooling, the peritectic reaction was incomplete, and no noticeable quantities of the β - γ eutectic were formed. Instead, the last liquid to solidify formed the nonequilibrium eutectic of δ in β , which characterizes the arc-melted alloy structures in this composition range.

Solid-State Equilibria

Intermediate Alloy Range: Maximum solubility of manganese in β titanium is about 33 pct at the eutectic reaction temperature. At temperatures from 1175° to 550°C , the β -phase field is bounded by a wide two-phase field of β plus γ . Fig. 9a illustrates an alloy within this two-phase region.

All attempts to isolate the γ phase by homogenization treatments were unsuccessful. After soaking 100 hr at 1100°C , alloys containing 45.4 through 54.7 pct Mn show three-phase structures of β , γ , and δ as shown in Fig. 9b. Similar treatment on alloys with slightly higher manganese contents show that the γ - δ phase field extends from at least 56.4 pct Mn (Fig. 10) up to 66.9 pct Mn, which is the composition indicated for δ .

Titanium-Rich Alloys: The addition of manganese to titanium lowers the β transus sharply. McQuillan⁵

Fig. 3—Partial phase diagram for iodide titanium-manganese alloys.

indicates an even sharper drop in β transus than was found in the present work. Quenching from within the β field of alloys containing up through 5.1 pct Mn, produces acicular or martensitic transformation structures. At manganese contents of 6.4 pct and above, the β phase is retained by water quenching. These observations were corroborated by a determination of M_s temperatures by Duwez on titanium-rich alloys, which showed that the M_s temperature for the 6.4 pct Mn alloy is below room temperature. Fig. 11 illustrates the M_s curve obtained for these alloys.⁷

Manganese solubility in β titanium decreases progressively from a maximum of 33 pct at 1175°C to about 20 pct at 550°C where the β phase decomposes into α and γ in a very sluggish eutectoid reaction.

In an attempt to produce appreciable eutectoidal decomposition, wrought samples containing up through 24.5 pct Mn were annealed for 500 hr at 540°C . Also, several alloys over the range of 15.1 through 24.5 pct Mn were annealed for 1440 hr at 500°C after an initial β -quenching treatment. Neither of these treatments produced any recognizable eutectoid decomposition in the hypoeutectoid alloys containing up to, and including, 17.2 pct Mn. Fig. 12a shows a typical structure for these alloys which consist of the α and β phases. In the alloys containing 20.3 pct Mn and greater, both of the

Table I. Inflection Temperatures Obtained from Resistance-Temperature Curves

Manganese Content, Wt Pct	Inflection Temperature, $^\circ\text{C}$
3.66	856
13.3	697
20.5	319

above treatments produced a fine, aggregate structure, illustrated in Fig. 12b, at the β -grain boundaries in addition to precipitating a small quantity of γ particles within the β grains. X-ray diffraction patterns on samples of these alloys did not show a sufficient number of lines for the minor phases to allow positive identification. However, an extrapolation of the β -phase-field boundaries determined at higher temperatures indicates that the β field must terminate at about 20.0 pct Mn in a eutectoid reaction at about 550°C . On this basis, the fine β -grain-boundary aggregate in the hypereutectoid alloys has been identified as the first sign of what must be a very sluggish eutectoidal decomposition. Metallographic data indicate that the α solubility of manganese reaches a maximum of about 0.5 pct Mn at 550°C .

Due to the slow rates of the reactions involved and to contamination incurred in spot-welding, resistance-measurements were not as satisfactory a means of following the phase transformations as were metallographic methods. Resistance-temperature curves obtained for three alloys showed inflections at the temperatures noted in Table I.

The inflections noted for the two lower manganese-content alloys are in fair agreement with the respective β transus temperatures determined metallographically. The inflection noted at 319°C for the 20.5 pct Mn alloy probably represents the beginning of β decomposition for this alloy under these particular conditions and has no direct significance. None of the resistance-temperature curves showed

inflections indicative of the eutectoid reaction temperature.

An interesting side observation from this work was that the apparent temperature coefficient of resistance of the β phase decreases with increasing manganese content until, at some composition between 3.66 and 13.3 pct Mn, it becomes negative.

X-Ray Diffraction

Diffraction patterns on alloys with low-manganese content showed the small amount of manganese taken into solid solution in the α phase had no significant effect on the α lattice parameter of unalloyed titanium.

Fig. 13 shows the results of X-ray diffraction measurements of the β lattice parameters of several alloys. The data show some scatter, which is probably due to lack of equilibrium, but indicate a linear relationship between the parameter and composition of the β , in accordance with Vegard's law.

The only one-phase alloy structure directly available for use in X-ray identification of the two Ti-Mn

compounds was that of the 66.9 pct Mn alloy, pictured in Fig. 5, which consisted predominantly of the single-phase δ . However, the diffraction pattern for this alloy gave similar lines to those obtained for alloys containing from 53.6 to 66.9 pct Mn. Metallographic examination showed that both the γ and δ phases were present in these alloys.

Fig. 8—Structure of a 53.6 pct Mn alloy slowly cooled through the solidification range. Since all attempts to prepare a single-phase γ structure by equilibration treatments were unsuccessful, a diffusion couple was prepared to isolate the phases. This couple was made by heating contacting samples of electrolytic manganese and a 20 pct Mn alloy in a Vycor capsule under argon for two weeks at 1000°C. Metallographic examination of the original interface between the samples showed that at least two, and perhaps three, compounds are formed between titanium and manganese. An X-ray diffraction film taken from the first compound layer adjacent to the 20 pct Mn alloy (i.e., the γ -compound layer) showed the pattern given in Fig. 14. Subtraction of these lines from the pattern obtained for the 66.9 pct Mn alloy left the lines shown in Fig. 14 as being those characteristic for the δ compound. These patterns were consistent with the metallographic structures and diffraction patterns for alloys containing 53.6 through 66.9 pct Mn.

The pattern for the δ compound is identical to that reported by Wallbaum⁸ for the compound TiMn₂. This investigator found a hexagonal structure of the C14 type (MgZn₂) with a and c parameters of 4.18Å and 7.88Å, respectively. The composition indicated for the δ or TiMn₂ compound by the present work is 66.9 pct Mn rather than 69.6 pct Mn which corresponds to the stoichiometric ratio. As shown in Fig. 6b, an alloy containing 69.5 pct Mn is well within a two-phase field of δ plus a new higher manganese-content phase.

The crystal structure for the γ phase has not been identified. Although the indicated composition for this phase corresponds roughly to TiMn, the diffraction pattern observed does not fit the body-centered cubic CaCl₂-type lattice observed⁸ for the

Summary

A phase diagram for alloys containing 0 to 69.5 pct Mn was determined using iodide titanium as the base material. Two compounds, tentatively labeled δ and γ , exist within this composition range.

The δ compound is located at about 66.9 pct Mn and melts congruently at 1330°C. The γ compound has a composition near 53 pct Mn and originates in a peritectic reaction at 1200°C between δ and melt containing 45 pct Mn.

β titanium, containing 33 pct Mn, and γ undergo a eutectic reaction at 1175°C, with the eutectic composition located at 42.5 pct Mn. Manganese solubility in β titanium decreases almost linearly from a maximum of 33 pct Mn at 1175°C to about 20 pct Mn at 550°C where the β phase decomposes,

Fig. 12—Structure for a hypo- and hyper-eutectoid alloy quenched from 800°C and reheated to 500°C for 1440 hr. Etchant: 1 pct HF, 3 pct HNO₃ in water. X500. in a very sluggish eutectoid reaction, into α and γ . Increasing additions of manganese to titanium lower the β transus to 550°C at the eutectoid composition. The solubility of manganese in α titanium reaches a maximum of about 0.5 pct Mn at the eutectoid temperature.

Acknowledgments

The authors are grateful to the Research Division of the Materials Laboratory at Wright-Patterson Air Force Base for permission to publish this work, which was performed at Battelle Memorial Institute under their sponsorship. The authors also wish to thank O. J. Huber and J. R. Doig, of Battelle, for the X-ray diffraction work reported, and M. W. Mallett, of Battelle, for his assistance in the determination of the melting range in the Ti-Mn system.

Appendix—Experimental Methods

Materials: Iodide titanium crystal bar and electrolytic manganese were used in the preparation of these alloys. The titanium was supplied in several lots by the New Jersey Zinc Co. to the specification that the maximum hardness should not exceed 85 Vickers. A typical spectrographic analysis for one of these lots is given in Table II.

Analysis for the as-received manganese was as follows: N, 1 part per million; H, 120 parts per million; sulphide sulphur, 0.014 pct; sulphate sulphur, <0.001 pct; and Fe, <0.001 pct. Prior to use in alloying, the manganese was arc-melted under a total pressure of 10 cm of argon to remove the absorbed hydrogen.

Melting Procedure: All alloys were prepared by direct arc melting of charges of iodide titanium and premelted electrolytic manganese, under a total pressure of 10 cm of argon, and on a water-cooled copper hearth. This furnace and the procedure for con-

tamination-free melting have been adequately described elsewhere in the literature.^{4,9} Ingot size was generally held to about 15 g. In order to minimize manganese losses during melting, current input to the arc was maintained at about 200 amp, and the time of a single melt was limited to about 5 min. Three such melts were generally found adequate to obtain complete melting of all ingots prepared, with each ingot being flipped over between melts. Some weight losses were incurred during melting. Compositions calculated on the assumption that the weight loss was entirely manganese agreed within ± 1.0 pct of the analyzed compositions. However, all compositions were checked by chemical analysis. An excess of 0.5 to 1.0 pct Mn above the desired composition was generally sufficient compensation for losses during melting.

Fabrication: Upset forging and hot rolling in air were used for breaking down the cast ingots wherever possible. Ingots containing through 7 pct Mn were fabricated to 0.060-in. strip by the use of this procedure at 750°C. For the higher manganese-content ingots, 850°C was used. At this temperature, an alloy containing 20.5 pct Mn was the highest manganese-content alloy which could be fabricated. Alloys containing 23.2 pct Mn and above could not withstand forging and cracked badly after the first few passes during attempted hot rolling.

After rolling, each strip was given a 15-min strain-relief anneal at rolling temperature and air cooled. As a precaution against surface contamination, all strips were cleaned by grit blasting and pickling in a 20 parts HF, 80 parts HNO₃ (by volume) bath to remove a total thickness of 0.004 in.

Heat Treatment: All quenching treatments were carried out using chromel-A-wound, Type 304 stainless steel tube furnaces. Gettered argon was admitted through one end of the tube as an atmosphere to protect the samples during treatment. The furnace was mounted in a cradle which pivoted about an axis through the open end of the furnace tube. Samples for treatment were placed in a titanium-sheet sleeve packed with titanium turnings. Quenching of the sleeve and samples were effected by up-ending the furnace and sliding the sleeve out of the tube into a bucket of water. Temperature control in these furnaces was maintained within $\pm 3^\circ\text{C}$.

For homogenization treatments, Globar and molybdenum-wound McDanel tube furnaces were used. These furnaces were adapted to receive argon, and temperatures were controlled within $\pm 10^\circ\text{C}$.

Wherever possible, metallographic samples were cold-rolled before heat treatment to expedite attainment of equilibrium structures. The degree of cold reduction varied from 50 pct, for the lowest manga-

Table III. Time Schedule for Equilibrating Treatments

Temperature Range, °C	Time, Hr
1100	1
1000-1050	2
900-1000	4
800-900	6
775-800	12
750-775	16
700-750	24
570-700	168

nese-content alloys, to 35 pct, for the 20.5 pct Mn alloy. Initially, the time schedule shown in Table III was selected for equilibrating treatments.

Subsequently, several longer time treatments were used to explore critical composition ranges at various temperature levels. Alloys bordering the eutectoid composition were given treatments of 200, 300, 500, and 1440 hr at the respective temperatures of 650°, 600°, 540°, and 500°C. Also, 100-hr treatments were used in equilibrating alloys containing above 25 pct Mn, at temperatures from 925° through 1100°C.

All quenching treatments were carried out under an argon atmosphere. For treatments extending beyond 24 hr, Vycor capsules were used. In these instances, the samples were wrapped individually in columbium foil, and the capsules sealed under a partial pressure of argon.

The alloys containing above 20.5 pct Mn were too brittle to permit either hot or cold-working. Consequently, ingots containing from 20.5 pct to 69.5 pct Mn were given 100-hr homogenization treatments at temperatures ranging from 975° to 1100°C.

Metallography: Samples for metallographic examination were prepared by hand grinding on 240X, 400X, and 600X wet papers. Grinding scratches from the 600X paper were removed by using a slurry of Linde B alumina and chromic acid on either a Forstmann or Miracloth lap on a high-speed (1725 rpm) wheel. Final polishing was done using Linde B alumina on a Microcloth lap on a medium-speed wheel.

An etchant composed of 1 pct HF and 3 pct HNO₃ (by volume) was generally satisfactory for all structures examined. Some difficulty was experienced, however, in differentiating between the phases present in the alloys containing 45 to 55 pct Mn. For these structures, a supplemental heat-tinting procedure proved quite useful. This was accomplished by heating the chemically etched samples for 5 min in air at 425°C. This procedure caused selective oxidation and discoloration of the γ and δ compounds, but left the β phase relatively unchanged.

Resistance Measurements: Electrical resistance measurements were investigated as a means for checking the transformations in the titanium-rich alloys. In this work, a set of current and potential leads were spot welded to a sheet sample surrounded by titanium turnings in a titanium sleeve. This assembly was placed in a tube furnace and heated at a rate of 0.25° to 0.50°C per min, using gettered argon as an atmosphere. Current to the sample was held at 1.00 ± 0.01 amp. Alternate readings of temperature and the potential drop across the sample were taken at intervals of 1 min and used to construct a resistance vs temperature curve for each of the alloys investigated.

X-Ray Diffraction: For precision measurement of the α and β lattice parameters as well as for diffraction work on the γ and δ compounds, samples were photographed in a 114.6 mm Debye camera. The α patterns were prepared using copper radiation with a 1 mm aluminum foil being interposed to reduce the high background normally produced with titanium. The values taken for the wavelengths of the characteristic copper K α_1 and K α_2 radiations were 1.54050 and 1.54434Å, respectively.

For the other diffraction work in the Debye camera, unfiltered vanadium radiation was used. The values taken for the wavelengths of the characteristic vanadium K α_1 , K α_2 , and K β radiations were 2.5072, 2.5034, and 2.2843Å, respectively.

All parameter calculations were based on the Cohen extrapolation method, with the Gauss method being used to calculate the probable error. Spectrometer charts were also prepared on occasional samples to check the metallographic phase identification.

Melting Range Determinations: Initial investigation of the melting range was carried out by observation and optical temperature measurement of block samples induction heated under argon. For fabricable alloys, sheet samples bent into V shapes were used, and

for brittle alloys, wedge-shaped pieces of the fractured ingots were selected. In either case, the sample was placed in a deep-well graphite crucible so that observation could be made on a thin, angular section during heating. Solidus temperatures were approximated by noting the temperature at which rounding of edges or slumping of the sample occurred. Liquidus temperatures were obtained with an estimated accuracy of $\pm 10^\circ\text{C}$ by noting the temperature at which complete collapse of the sample occurred. As a check point, the melting point of electrolytic nickel was determined as 1450°C using this equipment. This compares favorably with the handbook value of 1455°C. Using a similar procedure, the melting point of unalloyed, iodide titanium was determined as 1680° $\pm 10^\circ\text{C}$.

Thermal analysis was used to investigate the liquid-solid relationships in the intermediate alloy range. Samples of approximately 10 g were charged in graphite crucibles 1 1/16 in. in length with an outside diameter of 3/4 in. and a wall thickness of 1/16 in. Temperatures were measured using a calibrated Pt-Pt-10 pct Rh thermocouple inserted in a thin-walled graphite-crucible well. Heating and cooling curves were obtained directly through use of a General Electric recording millivoltmeter. Thermal arrests obtained during the initial run on each sample were rechecked by selecting a higher range of sensitivity on the recorder and repeating the run.

Reaction between the crucible and melts containing from 33.2 to 58.0 pct Mn was largely restricted to the graphite interface, although a small number of carbides appeared scattered through each melt. Reaction between the graphite and melts containing above 63.2 pct Mn was, however, very severe. In the thermal analysis of a 66.4 pct Mn alloy, it was only possible to obtain one cooling curve because of the rapid rate of reaction of the graphite and melt.

Determination of M_s Temperatures: Laboratory work on the determination of M_s temperatures for six titanium-rich manganese alloys was performed in a cooperative effort by Pol Duwez at the Jet Propulsion Laboratory, California Institute of Technology. The equipment and procedures used by Dr. Duwez have been described in detail in a previous publication.¹⁰

Titanium-Tungsten and Titanium-Tantalum Systems

by D. J. Maykuth, H. R. Ogden, and R. I. Jaffee

Phase diagrams for the Ti-W and Ti-Ta systems were determined. The Ti-W system is characterized by a wide, two-phase region of β plus tungsten which is derived from a peritectic reaction between the liquid and tungsten solid solutions. The β field terminates in a eutectoid reaction between α titanium and tungsten terminal solid solution. Tantalum and β titanium form a complete series of solid solutions. Other features of this system are the extensive α - β field at low temperatures and an appreciable solubility of tantalum in α titanium.

BOTH tungsten and tantalum were first thought to form β -isomorphous systems with titanium as a result of early work¹ using powder-metallurgical techniques. Later work² on arc-melted Ti-Ta alloys, made using a commercial titanium base, showed that, in the range of 0 to 10 pct, tantalum was soluble in β titanium and that the α solubility extended to between 2 and 5 pct Ta at 790°C.

The present investigation covered the entire alloy range in both systems and was chiefly concerned with high-purity alloys at the titanium-rich end. The constitution of titanium-rich alloys made with a commercial titanium base was reported by Holladay, Kura, and Jackson.^{3, 4} As will be shown in detail later, the early prediction of β isomorphism was true for the case of the Ti-Ta system, but not for the Ti-W system. The results of this investigation will be presented first. The experimental methods used are described in the Appendix.

Ti-W System

The entire Ti-W phase diagram is shown in Fig. 1. Details of the titanium-rich side are shown in Fig. 2. The chief features of the system are a β eutectoid and a high-temperature peritectic between liquid and tungsten solid solution.

Melting Range: Examination of cast structures of low and medium-tungsten-content ingots showed cored β phase as the primary constituent. Fig. 3a illustrates a typical cast structure for alloys in the range of 20 to 30 pct W. From 30 to 72 pct W, coring was very severe. Alloys containing 72 through 88 pct W, however, showed definite evidence of a peritectic reaction between the liquid and a terminal solid solution of titanium in tungsten. Fig. 3b shows the cast structure for an 80 pct W alloy. A 95 pct W alloy, shown in Fig. 4, consisted primarily of primary tungsten solid solution plus a small quantity of β probably rejected during cooling.

Incipient-melting experiments located the peritectic temperature between 1850° and 1900°C and indicated that the reacting phases are liquid containing about 25 pct W and tungsten terminal solid solution containing about 8 pct Ti. Figs. 5 and 6

Fig. 1—Phase diagram for the Ti-W system.

illustrate typical structures obtained in these experiments. The peritectic composition was placed at slightly above 50 pct W.

Solid-State Equilibria: Tungsten solubility in β titanium decreases from a maximum of about 50 pct at the peritectic temperature to about 28 pct at about 715°C, where the β phase decomposes eutectoidally. Additions of tungsten to titanium depress the β transus from 882° to 715°C at the eutectoid composition. On quenching alloys containing up through 20 pct W from the β field, martensitic β transformation structures are produced. At compositions of 25 pct W and greater, the β is completely retained on quenching. Metallographic data bracket the eutectoid composition between 25 and 30 pct W, and 28 pct W was taken as the numerical value.

A few spot checks using electrical-resistance measurements have roughly checked the transus temperatures found metallographically. These were done in hypoeutectoid alloys. However, because contamination occurred in spot welding leads to the specimens, and because of the sluggishness of the reactions involved, resistance-measurement did not afford a reliable means of following the phase transformations. No inflections in the resistance-temperature curves were observed at the eutectoid temperature, presumably because of reaction sluggishness. The eutectoid-reaction temperature was bracketed between 700° and 725°C by metallographic examination of heat-treated specimens. The heat treatments used consisted both of isothermal transformation after quenching from the β field to the test temperature and also conventional equilibrating annealing treatments on wrought specimens. Figs. 7 through

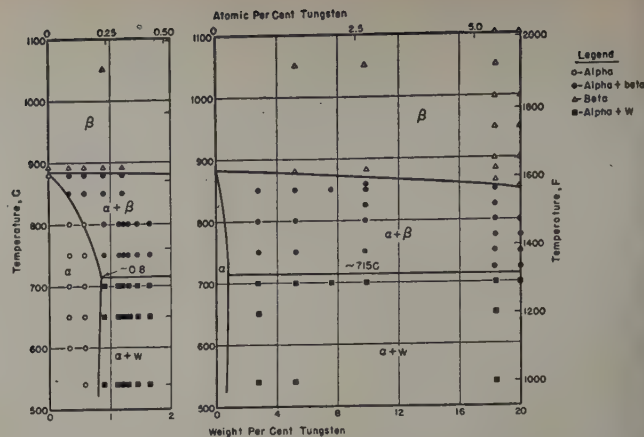

Fig. 2—Partial phase diagram for iodide titanium-tungsten alloys.

11 show typical structures produced in alloys on both sides of the eutectoid by isothermal treatments.

Annealing both hypoeutectoid and hypereutectoid alloys at 700°C and lower temperatures produced the dark-etching structure shown in Figs. 8 and 10. Hypoeutectoid alloys isothermally treated at temperatures within the α - β field contained Widmanstätten α structures of the type shown in Fig. 7.

Hypereutectoid alloys in the range of 30 to 50 pct W showed two distinctive modes of tungsten precipitation as a result of isothermal heat treatments above the eutectoid temperature. The bulk of the precipitated tungsten took the form of small particles or plates. However, as illustrated in Figs. 9 and 11, there was appreciable precipitation of tungsten at the β grain boundaries in the form of fan-shaped colonies. These colonies resemble a eutectoidal decomposition product, but as Figs. 9 and 11 show, the phase within the fan arrangement, adjacent to the tungsten plates, is continuous with the parent β matrix. None of this lamellar-type precipitate was observed in any of the higher tungsten-content alloys at any of the temperatures investigated.

X-ray confirmation on the eutectoid-reaction products was also obtained. Diffraction patterns on samples of an 18.4 pct W sample annealed for 1000 hr at 540° and 650°C showed patterns for α titanium and a body-centered cubic phase with a parameter of 3.164Å. This cubic structure was identified as the terminal tungsten solid solution which has been expanded from 3.158Å by the solution of a small quantity (less than 5 pct) of titanium.

The maximum solubility of tungsten in α tita-

Ti-Ta System

Fig. 12—Phase diagram for the Ti-Ta system.

nium, determined metallographically, is about 0.8 pct at 715°C (cf. Fig. 2). Tungsten in solid solution in α titanium was found to have practically no effect on lattice parameter. Hence, the X-ray method was not useful in determining α solubilities. The solubility of titanium in tungsten decreases from a maximum of about 8 pct at the peritectic-reaction temperature to less than 5 pct at temperatures in the region of the eutectoid. These conclusions are based on microexaminations of as-cast and heat-treated high-tungsten alloys.

Structures in the composition range around the eutectoid were sensitive to heat treatment in that they clearly showed the eutectoid reaction. As the tungsten content increased, however, the β eutectoidal decomposition reaction became increasingly sluggish. Even after isothermal treatment of 300 hr at 700°C, samples containing 36 and 40 pct W showed an increasing amount of undecomposed β phase. Heat treatments at 700°C on alloys containing 88 and 95 pct W showed no metallographic evidence of β eutectoid decomposition.

As mentioned earlier, homogenization treatments failed to produce equilibrium structures in alloys containing above 40 pct W. However, the phase distributions and structures observed were consistent with the lower alloy-content samples over the temperature range investigated.

Fig. 13—Partial phase diagram for iodide titanium-tantalum alloys.

The phase diagram for the entire range of compositions in the Ti-Ta system is shown in Fig. 12. The titanium-rich portion is shown in Fig. 13. β titanium and tantalum form a continuous series of solid solutions. The α field, although closed, has an appreciable range.

Melting Range: Both optical observation and incipient-melting techniques were used to determine the melting range. The solidus curve rises smoothly from the melting point of titanium to that of tantalum. The solid-liquid range is seen to be relatively narrow. Fig. 14 illustrates a typical partially melted alloy, showing how the incipient-melting technique was applied to obtain the solidus curve at the higher alloy contents.

As-cast structures for an alloy series containing 40 to 95 pct Ta were consistent with the isomorphism of β titanium and tantalum in that they consisted entirely of cored β phase.

Solid-State Equilibria: Examination of alloys containing from 0.96 through 95 pct Ta equilibrated at 1000°C confirmed the existence of complete β solid solubility. Fig. 15 shows a typical β -transformation structure and a retained- β structure for alloys quenched from this temperature. Some slight in-

Fig. 14—Incipient melting in a 80 pct Ta alloy heated to 2250°C for 5 min and furnace cooled. Large equiaxed β grains with "burnt" spots indicating incipient melting. Etchant: 1 pct HF, 3 pct HNO₃ in water. X100. Area reduced approximately 50 pct for reproduction.

homogeneity persisted in the alloys containing 40 through 60 pct Ta even after homogenization treatment. This was indicated by nonuniform α precipitation in these alloys at temperatures below the β transus. No evidence of β decomposition was observed in the alloys containing 80 through 95 pct Ta at temperatures down through 600°C.

Tantalum additions to titanium depress the β transus gradually. β quenching of alloys containing up to 40 pct Ta produces martensitic transformation structures, like that shown in Fig. 15a. At tantalum contents of 50 pct and above, the β phase was retained on quenching.

As indicated in the phase diagram, tantalum shows an appreciable solubility in α titanium. This increases with decreasing temperature to about a

Table I. Lattice Parameter Data for Three Ti-Ta Alloys

5.36	2.9502±0.0003	4.6873±0.0002	1.589

Fig. 15—Structures for two Ti-Ta alloys quenched after 24 hr at 1000°C. Etchant: 1 pct HF, 3 pct HNO₃ in water. X250. Area reduced approximately 50 pct for reproduction. a (left)—40 pct Ta. Large equiaxed β grains with martensitic needles of α . b (right)—80 pct Ta. Large equiaxed β grains.

maximum of 12.5 pct Ta at 550°C. α parameters determined for three alloys annealed 14 days at 530°C showed that tantalum expands the α -titanium lattice in the c direction while showing no significant effect on the a parameter. These data are given in Table I. Although the graphical relationship of c parameters to alloy composition was approximately linear, the scatter along this line was too large to permit use of parameter measurements in locating the α transus.

Resistance-temperature curves for three alloys showed inflections at the temperatures noted in Table II. These data provided a rough check for the metallographic determination of the transus tem-

Mines titanium as a base for the intermediate and high-alloy ranges.

Liquid (containing about 25 pct W) and tungsten solid solution (containing about 8 pct Ti) react peritectically at about 1880°C to produce a wide two-phase region of β -tungsten in the intermediate portion of the diagram. The solubility of titanium in tungsten decreases from about 8 pct Ti at 1880°C to slightly less than 5 pct Ti at around 700°C.

Tungsten solubility in β titanium decreases from a maximum of about 50 pct W at 1880°C to about 28 pct W at 715°C, where the β -phase field terminates in a eutectoid reaction between α titanium and tungsten terminal solid solution. Increasing

perature, which represented a much closer approach to equilibrium conditions. Fig. 16 shows typical two-phase structures for alloys equilibrated within the extensive α - β field.

X-ray diffraction patterns on two alloy samples of a 27.2 pct Ta alloy annealed 1000 hr at 540° and 650°C showed lines for α titanium and a body-centered cubic phase which represented β solid solution. Line intensities of these patterns, however, were not sufficient to permit accurate parameter measurements.

Summary

Binary phase diagrams for the Ti-W and Ti-Ta systems were determined using iodide titanium as a base for the titanium-rich alloys and Bureau of

additions of tungsten to titanium lower the β transus to 715°C at the eutectoid composition. Tungsten solubility in α titanium reaches a maximum of about 0.8 pct W at the eutectoid reaction temperature.

β titanium and tantalum form a complete series of solid solutions. Increasing additions of tantalum to titanium progressively increase the melting range and lower the β transus to 600°C at about 70 pct Ta. Tantalum solubility in α titanium increases with decreasing temperatures to a maximum of about 12.5 pct Ta at 550°C.

Acknowledgments

The authors are grateful to the Research Division of the Materials Laboratory at Wright-Patterson Air Force Base for permission to publish the results of this work, which was done at Battelle Memorial Institute under their sponsorship. They also wish to thank O. J. Huber and J. R. Doig, of Battelle, for the X-ray diffraction work reported in this paper, and M. W. Mallett, of Battelle, for his assistance in the determination of the melting ranges in both alloy systems investigated.

Appendix—Experimental Methods

Materials: Iodide crystal-bar titanium was used in preparing the titanium-rich alloys and U. S. Bureau of Mines powder titanium was used for the intermediate

Fig. 17—Crucible design for arc casting of Ti-W ingots.

and high-alloy ranges. The iodide titanium was produced by the New Jersey Zinc Co. to the specification that the maximum lot hardness should not exceed 85 Vickers. A typical spectrographic analysis for one of these lots is given in Table III.

The analysis furnished by the Bureau of Mines for the powder titanium was as follows: Fe, 0.15 wt pct; Mg, 0.30; Ca, 0.036; Si, 0.005; V, 0.012; and H, 0.25 pct or 25 to 30 ml per g.

The tungsten and tantalum used, both of 99.9+ pct purity, were produced by the Fansteel Metallurgical Corp. The tungsten used was in the form of 10-mil wire and as -200-mesh powder. Tantalum was available as 0.006-in. sheet and also as "Standard Reclaimed Powder."

Alloy Preparation: Preparation of homogeneous alloys of titanium with the high-melting, heavy metals, tungsten and tantalum, proved to be a difficult task, and the methods used merit special mention here. Initially, alloys containing up through 18.4 pct W were prepared by direct arc melting charges of iodide titanium crystal bar and 10-mil tungsten wire on a water-cooled copper hearth in a small, tungsten-arc furnace. This furnace and the melting procedure used have been previously described.^{4,5} Because of the refractory nature of tungsten, a rigorous schedule of sectioning and remelting the ingots was necessary to insure complete solution of the tungsten. The total number of melts required was roughly proportional to the tungsten content, with a maximum of 12 melts being required for the 18.4 pct W alloy.

In order to evaluate the higher tungsten-content alloys, samples were prepared using powdered titanium and tungsten. Compacts with compositions ranging from 20 through 95 pct W were pressed and vacuum sintered to remove the magnesium chloride and hydrogen present in the powder. Melting of the compacts containing from 20 through 60 pct W was carried out in a small vacuum-arc-furnace unit with the maximum current capacity of 500 amp being required for the 60 pct W alloy. In order to obtain complete melting of the higher alloys, an arc furnace with a higher current capacity was used. This furnace utilized a spun-copper crucible and operated under a positive pressure of argon. A complete description of the furnace and melting procedure used has been described.⁶

Another method of preparing homogeneous Ti-W alloys was also tried. In hopes of circumventing the arduous sectioning and melting procedure required to insure complete melting of alloys made of tungsten wire and iodide titanium, porous, presintered chunks

of tungsten were used as the alloy addition. Six alloy charges, containing 20 through 40 pct W, were given an initial consolidating melt under argon. The alloys were then given three additional melts under helium, which provides a hotter arc than argon, to complete alloying of the titanium and tungsten. In order to eliminate the freezing segregation, the alloys containing 24 through 40 pct W were given a final melting operation during which they were cast in a cylindrical crucible of the design shown in Fig. 17. Casting was accomplished by placing an ingot over the hole on the split copper block and by directing the arc to the sample until melting occurred. The ingot then flowed into the graphite receptacle below.

Subsequent examination of the arc-cast ingots showed that, while homogeneous and uniform structures were obtained in the 32, 36, and 40 pct W alloys, severe segregation still persisted in the 24 and 28 pct W ingots as a carry-over from the initial melting. Failure of arc casting to overcome this segregation may be because of the lower melting range of these alloys and their increased fluidity.

Alloys containing up through 27.2 pct Ta were prepared by direct arc melting charges of iodide titanium crystal bar and tantalum sheet. Melting of these alloys was only slightly less difficult than for the corresponding earlier Ti-W alloy series. By repeated sectioning and remelting, complete solution of the tantalum was obtained.

Evaluation of alloys in the range of 40 through 95 pct Ta was carried out using samples prepared from titanium and tantalum powders. These powder alloys were processed in the manner described for the similar Ti-W series. All of the Ti-Ta alloys were successfully melted in the small vacuum-arc furnace under a total pressure of 10 cm Hg of argon.

Compositions for the alloys containing up through 18.4 pct W and 27.2 pct Ta were determined by chemical analysis. Because no satisfactory analytical techniques were available for the higher tungsten and tantalum-content alloys, these compositions were determined by weight-change measurements during melting. Weight losses for the alloys containing up through 60 pct W and 95 pct Ta during melting were less than 1 pct, and the use of nominal compositions for these alloys was justified on that basis. The alloys with above 60 pct W were melted in the larger arc furnace, and considerable spattering took place. Here, density measurements were made, and compositions were calculated using the law of mixtures. These checked the intended analyses very well.

Fabrication: Upset forging and hot rolling in air were used, where possible, to break down and homogenize the as-cast structures. Ingots containing up through 9.9 pct W and 9.1 pct Ta were successfully fabricated to 0.060-in. strip at 750°C.

For the 18.4 and 20 pct W alloys, it was necessary to increase the rolling temperature to 850°C to avoid edge cracking. An alloy containing 40 pct W could not be hot worked at 980°C, and fabrication attempts for this and the higher alloys were abandoned.

Alloys containing 17.9 and 27.2 pct Ta were fabricated at 850°C. Experiments on higher tantalum-content alloys indicated that increasingly higher working temperatures were required as the tantalum content increased. At 60 pct Ta, 980°C proved satisfactory, but an 80 pct Ta alloy cracked badly during fabrication attempts at this temperature. In the interest of minimizing contamination, fabrication attempts on alloys containing above 40 pct Ta were abandoned.

After hot rolling, each strip was given a 15-min strain-relief anneal at rolling temperature and air cooled. The rolled strips were then descaled by mechanical grinding and pickling in a 20 pct HF, 80 pct HNO₃ (by volume) bath to remove a total thickness of 0.004 in.

Heat Treatment: Prior to heat treatment, all of the alloys containing up through 20 pct W and 27.2 pct Ta were given cold reductions of 50 pct to expedite equi-

Table IV. Schedule Adopted for Equilibrating Treatments

Temperature Range, °C	Time, Hr	Temperature Range, °C	Time, Hr
1000-1050	2	800-850	16
950-1000	4	750-800	20
900-950	8	700-750	24
850-900	12	570-600	168

librium structures. In order to minimize the severe coring obtained at the higher alloy levels, the tungsten and tantalum alloys were given a minimum of three, short-time, very high-temperature treatments in the vacuum arc-melting furnace. The currents used were sufficient to heat the ingots close to their melting points. These alloys were then encapsulated in Vycor under a partial pressure of argon and given further homogenizing treatments at 1000°C. A period of 100 hr at 1000°C was used for the Ti-W alloys and 24-hr treatment was given the Ti-Ta series. Examination of these alloys after the above treatment showed that homogeneous structures were obtained in all the Ti-Ta alloys and for compositions up through 40 pct W. At 45 pct W and above, uniform structures were produced, but complete equilibrium between the phases had not been obtained.

Initially, the schedule shown in Table IV was adopted for equilibrating treatments.

After the basic features of the Ti-W system had become apparent, additional treatments for these alloys were given as shown in Table V.

Treatments at 1800°C and above were carried out under argon in a high-frequency induction furnace. Samples were suspended individually by tungsten wires from the cover of a graphite crucible. Temperatures were measured optically, with an accuracy of $\pm 10^\circ\text{C}$, by sighting into a $\frac{1}{8}$ -in. ID hole, 9/16 in. deep, which had been drilled into a graphite pedestal on the crucible base. Unfortunately, no means of quenching samples from temperature was available with this furnace.

At 1400°C, heating was performed in a molybdenum resistance furnace of a design which has been described.⁷ Quenching from this temperature was effected using a silicone oil as the coolant.

All other quenching treatments were carried out in a chromel-A-wound, type 304 stainless steel tube furnace. Samples for treatment were packed in titanium turnings inside of a titanium-sheet sleeve and controlled within $\pm 3^\circ\text{C}$ at temperature. These furnaces were mounted in cradles which pivoted about an axis through one end of the furnace tube. Quenching was effected by up-ending the furnace and sliding the sleeve and samples into a water-filled quench pot.

All treatments beyond 24 hr were made using Vycor capsules and individual columbium-foil wrappers for the samples as protection against contamination by silica. In these and in all of the furnace treatments, gettered argon gas was used as an atmosphere.

Metallography: Metallographic samples were prepared by hand grinding on 240X, 400X, and 600X wet papers. Grinding scratches were removed by polishing with a slurry of Linde B alumina and chromic acid on a Miracloth lap on a 1725-rpm wheel. Final polishing was accomplished with Linde B alumina on a Microcloth lap on a medium speed wheel.

An aqueous solution of 1 pct HF and 3 pct HNO₃, by volume, was satisfactory as an etchant for all structures examined.

Table V. Additional Treatments for Ti-W Alloys

Temperature, °C	Time, Hr	Temperature, °C	Time, Hr
1800	1-4	750	200
1400	6	725	250
775	180	700	300

Resistance Measurements: Resistance measurements were investigated as a means of locating phase transformations in titanium-rich alloys of both systems. Current and potential leads (of molybdenum and Alumel wire, respectively) were attached to sheet-alloy samples by spot welding. The sample was surrounded by titanium turnings in a titanium sleeve and heated in a tube furnace under a gettered argon atmosphere at a rate of 2.0° to 2.5°C per min. Current through the sample was maintained at 1.00 ± 0.01 amp. Alternate readings of temperature and the potential drop across the sample were taken at 1-min intervals and used to construct temperature-resistance curves for the alloys investigated.

X-Ray Diffraction: Films for the α -lattice-parameter determinations on the alloys in both systems were made in a 114.6-mm Debye camera using copper radiation. A 1-mil aluminum foil was interposed to reduce the high background normally produced with titanium. The values used for the characteristic copper $K\alpha_1$ and $K\alpha_2$ radiations were 1.54050 and 1.54434Å, respectively.

In other parameter work, unfiltered vanadium radiation was used, again utilizing the 114.6 mm Debye camera. The values used for the characteristic $K\alpha_1$, $K\alpha_2$, and $K\beta$ radiations of vanadium were 2.5072, 2.5034, and 2.2843Å, respectively.

All parameter calculations were made using Cohen's graphical method. The Gauss method was used to calculate probable errors.

Melting Range: Liquidus and solidus temperatures for titanium-rich alloys in both systems were determined by optical observation on small samples induction heated under argon. Sheet samples of selected alloy compositions were bent into "V" shapes and inserted in deep-well graphite crucibles so that observations at the apex of the "V" could be followed during each run. Pyrometer readings taken at the first sign of rounding at the apex and at the point of the sample's collapse were interpreted as the solidus and liquidus temperatures, respectively. Using a similar procedure, the melting point of unalloyed iodide titanium was determined as $1680^\circ \pm 10^\circ\text{C}$.

Incipient-melting techniques were used to determine the liquid-solid relationships in the intermediate and high-alloy-content ranges. Metallographic samples were suspended individually by tungsten wires from the cover of a graphite crucible, as described earlier, and heated by induction to selected temperatures under argon. After treatment, the samples were mounted and examined metallographically for signs of melting. When melting in a given alloy sample was observed, succeeding samples were heated to progressively lower temperatures to bracket the solidus temperature. In this, as in other optical-pyrometer work, the accuracy of temperature measurement was estimated as $\pm 10^\circ\text{C}$.

Microstructure and Mechanical Properties of Iodide Titanium

by F. C. Holden, H. R. Ogden, and R. I. Jaffee

RECENT papers dealing with the properties of unalloyed iodide titanium have been directed primarily at the determination of base-line properties for alloy investigations. Early work was limited to a few tests because of the limited availability of iodide titanium at the time. In the results of papers by Campbell et al.,¹ Gonser and Litton,² Jaffee and Campbell,³ Finlay and Snyder,⁴ and Jaffee, Ogden, and Maykuth,⁵ data on mechanical properties are presented for unalloyed iodide titanium in the annealed and cold-worked conditions.

Data are presented in this paper which show the effects of heat treatment on the structure and mechanical properties of commercially produced iodide titanium. Correlation is made between microstructural variables and the mechanical properties.

Experimental Procedures

Melting Stock: The melting stock used was as-deposited iodide titanium, produced by New Jersey Zinc Co. The furnished analysis showed the following range of impurities: N, 0.004 to 0.008 pct; Mn, 0.005 to 0.013; Fe, 0.0035 to 0.025; Al, 0.013 to 0.015; Mo, 0.0015; Pb, 0.0045 to 0.0065; Cu, 0.0015 to 0.002; Sn, 0.001 to 0.01; Mg, 0.0015 to 0.002; and Ni, 0.003. Hydrogen content as determined by vacuum-fusion analysis was 0.0091 wt pct (0.44 atomic pct) after arc melting and fabrication. Nitrogen analysis on the arc-melted and fabricated titanium showed a content of less than 0.002 pct N. The average hardness of the furnished stock was R_t 70, or approximately 85 VHN.

Melting Procedure: The as-deposited rods were rolled, sheared, and degreased in preparation for arc melting. The charge was arc-melted with a tungsten electrode in a water-cooled copper crucible under a positive pressure of high purity (99.96 pct) argon. The final ingot was approximately 2 in. in diameter and showed no increase in hardness over that of the initial stock.

Fabrication: Heating for fabrication was done in air. It was begun by forging the ingot into a $\frac{3}{4}$ in. diam rod, at an initial temperature of 1600°F. Scale was removed by sandblasting. The rod was then swaged to $\frac{1}{4}$ in. diam at room temperature through a series of 20 dies, with approximately 10 pct reduction in area between each die. An anneal of 1 hr at 850°C in air was given after the $\frac{1}{2}$ in. die, such that the final cold reduction was 75 pct. Sections cut from this rod were used for test and microstructure specimens.

Discussion on this paper, TP 3482E, may be sent, 2 copies, to AIME by April 1, 1953. Manuscript, Sept. 15, 1952. Los Angeles Meeting, February 1953.

Fig. 1—Specifications for test specimens.

Heat Treatment: Heat treatments were carried out in resistance tube furnaces with stainless-steel linings, under an atmosphere of gettered argon. As further protection against contamination, the specimens were packed in titanium turnings in a titanium sleeve. Control experiments have shown negligible hardness increases with this method, indicating that contamination from oxygen and nitrogen is slight.

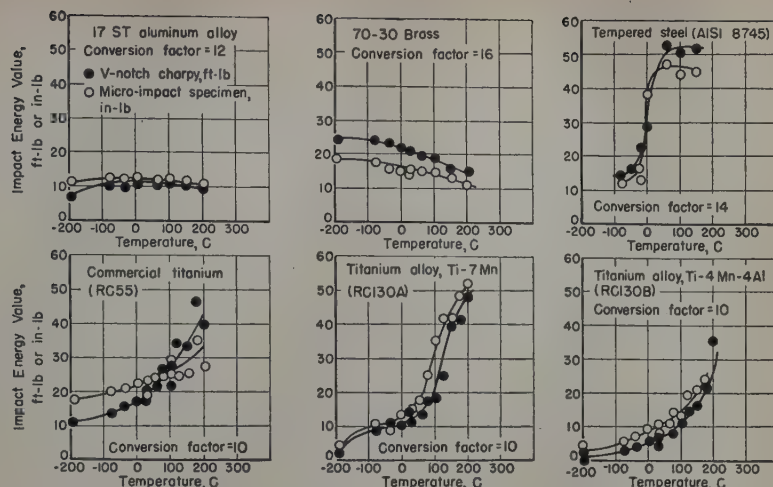

Three cooling rates were employed in this work; these have been designated as water quenching, argon cooling (to simulate air cooling under a controlled atmosphere), and furnace cooling. The cooling rate for an argon cool is 100°C per min for the first minute, with an average cooling rate of 35°C per min over a 15-min period. A furnace cool requires about 10 hr, with an average cooling rate of 3.6°C per min during the first hour, and an average cooling rate of 1.2°C per min over the 10-hr period.

Microimpact Test: The specimen adopted was based on the cylindrical Izod Type Y specimen (ASTM, E23-41T). All dimensions were reduced to half scale, including the notch radius. Specifications are shown in Fig. 1. The specimen is held vertically in an adapter and broken as a cantilever beam. Impact tests were run on a constant-velocity (11.34 ft per sec) Tinius Olsen impact testing machine with a total available energy of 100 in.-lb.

Tests were made to determine the correlation between this microimpact and the standard V-notch Charpy impact test. Curves showing impact energy as a function of temperature for both impact tests are plotted in Fig. 2. Transition temperatures, when they occur, are about the same for both impact tests. All three titanium-rich materials have the same conversion factor, 10.

Tensile Testing: Tensile tests were conducted on Baldwin-Southwark testing machines using the 600, 2400, or 3000 lb range. Specifications for the test specimen were taken from the 1948 edition of the ASM Metals Handbook, and are shown in Fig. 1. Strain measurements were made using an SR-4 resistance gage (Type A-7) cemented to the reduced section in conjunction with a lever-type extensometer. Readings on the SR-4 strain indicator were

Fig. 2—Comparison of microimpact and V-notch Charpy impact energy curves for various materials.

made up to about 2 pct elongation, and from the extensometer in 1 pct elongation increments up to about 50 pct elongation. Crosshead speeds were maintained at not over 0.005 in. per min until the limit of the SR-4 gage was reached, after which the strain rate was increased to 0.01 in. per min.

Metallography: The preparation of metallographic specimens involved mounting and wet grinding

Table I. Effect of Annealing Time and Temperature on the Grain Size of Alpha-Annealed Iodide Titanium*

* Tests made on material that had been arc-melted, forged at 850°C to 3/4-in. round, descaled, cold swaged to 1/2-in. round, annealed 1 hr at 850°C in air, descaled, cold swaged to 1/4-in. round (75 pct reduction in area), and given annealing treatments indicated, followed by argon cooling to room temperature.

through 600-grit paper. Polishing was done on a high-speed wheel with an abrasive of jewelers rouge, followed by a final polish on a slow-speed wheel with aluminum oxide. The usual etching reagents consisted of either a 5 pct solution of hydrofluoric acid in water or a 1 1/2 pct hydrofluoric-3 1/2 pct nitric acid solution. Early specimens were mounted in bakelite, but work by Craighead, Lenning, and Jaffee⁶ has shown that bakelite mount-

ing temperatures (up to 350°F) are sufficient to alter the solubility of the hydride phase in titanium, and thus affect the microstructure of the specimen. Accordingly, recent metallographic work was done on specimens mounted in a cold-setting plastic.

Alpha-Annealed Iodide Titanium

In the study of the effect of microstructure on the properties of a pure metal, the variables of interest are the effect of grain size and, for metals exhibiting allotropic transformation, the effect of different transformation structures. In this work the rate of cooling from both α and β anneals was found to influence the mechanical properties and microstructures, and, therefore, cooling rate has been included as a third variable.

Microstructure: Table I details times, temperatures, and resulting α grain sizes. α anneals produce equiaxed α with intragranular markings, which Craighead, Lenning, and Jaffee⁶ have shown to be titanium hydride. Fig. 3, which has been heavily etched to bring out the grain structure, is typical of the slow-cooled α -annealed structures with the Widmanstätten line markings. Figs. 4 and 5 illustrate the difference in dispersion of titanium hydride for α -annealed titanium after quenching and after slow cooling.

Mechanical Properties: The mechanical properties of α -annealed, argon-cooled iodide titanium are presented as functions of α grain diameter in Fig. 6. The effect of α grain size on the flow curves is shown in Fig. 7. These curves are not straight lines, and the flow coefficient B and flow exponent n in

Fig. 3—Specimen TMI-3, cold-reduced 75 pct, annealed 2 hr at 875°C, and argon-cooled. Equiaxed α structure, 0.10-mm average grain size. HF etch. X100. Area reduced approximately 45 pct for reproduction.

Fig. 4—Specimen TMI-12, cold-reduced 75 pct, annealed 1 hr at 800°C, and quenched. Equiaxed α structure with "salt-and-pepper" markings. HF-HNO₃ etch. X250. Area reduced approximately 45 pct for reproduction.

Fig. 5—Specimen TM2-1, cold-reduced 75 pct, annealed 1 hr at 800°C, and argon-cooled. Equiaxed α structure with Widmanstätten markings. HF-HNO₃ etch. X250. Area reduced approximately 45 pct for reproduction.

Fig. 6 (left)—Effect of grain size on the mechanical properties of α-annealed, high-purity titanium in the argon-cooled condition.

Fig. 7 (right)—Effect of grain size on the flow curves of α-annealed, high-purity titanium.

the flow equation $\sigma = B\epsilon^n$ are determined from the straight line extrapolation. These data show that, in line with expectation, increased grain size results in lower strength, higher ductility, and higher strain hardening, but the changes involved are relatively slight.

Impact-energy values for equiaxed α-annealed iodide titanium show a greater dependence on grain size, which is illustrated by the room-temperature impact-energy curve in Fig. 6.

The variation of impact energy with temperature can be observed for different grain sizes and cooling rates in Fig. 8. All curves show the same general configuration, with impact-energy values increasing slowly from -196°C up to room temperature, and

increasing rapidly above room temperature. It should be noted that all fractures observed were of the ductile or fibred type, and the impact-energy values are above any brittle-to-ductile transformation temperature. The increase in impact energy observed above room temperature is considered to be caused by an increasing absorption of energy in deforming the test specimen. Bending of the specimens can be observed clearly in those tested at the higher temperatures.

The effects of different cooling rates on the mechanical properties of α-annealed iodide titanium have been investigated. These studies include the effect of quenching as compared with argon cooling in the 0.10-mm and 0.20 to 0.25-mm α grain sizes,

Fig. 8—Effect of grain size and cooling rate on impact energy of α-annealed, high-purity titanium.

* Tests made on material that had been arc-melted, forged at 850°C to 3/4-in. round, descaled, cold swaged to 1/2-in. round, annealed 1 hr at 850°C in air, descaled, cold swaged to 1/4-in. round (75 pct reduction in area), and given annealing treatments indicated.

and the effect of furnace cooling as compared with argon cooling in the 0.05-mm α grain size. Tensile test data are presented in Table II, and impact-energy values are plotted in Fig. 8.

From these data, the quenched equiaxed- α specimens, as compared with those argon-cooled, show increased tensile and yield strengths and less tensile elongation. Greater impact-energy absorption is also found in the quenched condition. No significant difference is found between argon-cooled and furnace-cooled α -annealed specimens.

Transformed-Beta Iodide Titanium

Two cooling rates were used in the study of the transformed- β structures. These were a water quench and a furnace cool. All the anneals consisted of a 1-hr treatment at 1000°C, and the original β grain size was thus the same in each case. Microstructures and mechanical properties resulting from these treatments are presented and discussed in the following sections.

Microstructure: The appearance of the quenched structure is shown in Fig. 9, and that of the furnace-cooled structure in Fig. 10. The irregular outlines correspond to colonies of α plates with similar orientations. It may be observed that the α -colony outlines in the quenched specimen are more irregular than those of the furnace-cooled specimen. Although both maintain the serrated outline, the more slowly cooled structure has had time for growth of the α plates to a more regular outline. The difference in the amount and form of the intragranular marks again points to the presence of the second phase, titanium hydride. In the quenched structure, the marks have a "salt-and-pepper" appearance, being more finely divided than the Widmanstätten line markings observed in the furnace-cooled structure.

The structures observed after heat etching* are

* Heat etching is accomplished by heating a prepolished specimen at the desired annealing temperature in a protective atmosphere and cooling in that atmosphere. The grain boundaries present at temperature are clearly delineated by this method.

shown in Figs. 11 and 12. Fig. 11 shows the result of the formation of α colonies over a background of prior β grains. It should be observed that these α colonies do not conform to the original β grain outlines, as is more clearly shown in the heat-tinted†

† Heat tinting is accomplished by heating a prepolished specimen for a short time in air to stain the surface of the specimen. This stain has a color characteristic of the orientation of the α grain and a very good degree of contrast between α grains may be obtained in this way.

structure in Fig. 12. Here the dark areas conform to the α colonies and do not appear to have a direct relationship to the prior β grains. The rough appearance of the surface is caused by the volume change which accompanies the β -to- α transformation.

Mechanical Properties: Results of tensile tests on the transformed- β structures are given in Table III, and impact-energy values are plotted in Fig. 13. The quenched specimens have higher tensile and yield strengths and lower ductility, as indicated by elongation, than the corresponding furnace-cooled specimens.

Results of the impact-energy tests show a pronounced increase in impact energy for the quenched over the furnace-cooled condition, a result probably associated with the finer dispersion of titanium hydride. This effect was also noted for specimens quenched from the α field. Comparison of the microstructures of these two transformed- β structures shows that the only apparent differences are the regularity of the outlines of the serrated α colonies, and the form and dispersion of the intragranular markings. Since the difference in regularities of the serrated α colonies is small, it would appear that the

differences in tensile strength and impact energy are caused by the manner in which the second phase, titanium hydride, is distributed. Since the hydride is nearly insoluble at room temperature, but has high solubility above 300°C,⁶ its degree of dispersion will depend upon the rate of cooling through the hydride-precipitation range. Increases in tensile strength and Vickers hardness are slight, as a result of the almost negligible solubility of this phase in

Fig. 12—Specimen 1-5. Same as Fig. 11, followed by heat treating 5 min at 1100°F in air. Transformed β structure. X100. Area reduced approximately 45 pct for reproduction.

α titanium at room temperature. Thus, the dependence of these properties on the degree of dispersion is relatively insignificant. The marked difference in impact energy, however, indicates a considerable dependence of that property on the degree of dispersion of titanium hydride.

Summary

The gross structural features of iodide titanium are its grain size and grain shape, either equiaxed or serrated. In this work, the size of equiaxed α grains has been varied from 0.01 to 0.25 mm. The serrated α structure is the usual result of the β -to- α transformation, and, because of the large size of the β grains, serrated α grains are also quite large. There is also a fine structure in iodide titanium, which is attributed to the formation of titanium hydride whose solubility is very low at room temperature.

The degree of dispersion of the titanium hydride apparently has an important effect on impact-energy values: when the hydride is finely dispersed as a result of quenching, the impact-energy values are

higher than when the hydride is present as Widmanstätten line markings resulting from slow rates of cooling through the hydride-precipitation range.

Variation of the grain size of equiaxed α titanium from 0.01 to 0.25 mm, in the argon-cooled condition, produces relatively small changes in the tensile and impact properties. As grain size increases over this range, the strength and hardness decrease slightly and the ductility in the tensile test increases correspondingly. Flow curves show that the larger grain-size material work hardens considerably more than the fine-grain-size material, starting from a lower initial flow stress. Although all the iodide titanium tested in impact was above any brittle-to-ductile transition for temperatures down to liquid-air temperature, the level of impact energy absorbed did show variations with grain size.

Quenching from the α field, which changes the distribution of the titanium hydride, produced an increase in hardness and strength, particularly in the yield and flow stresses, and also increased the level of the impact energy.

Titanium with a large-grained serrated α structure produced by furnace cooling from the β field had mechanical properties very similar to those of titanium with equivalently large equiaxed- α grains. Quenching from the β field, which changed the intragranular fine structure to "salt and pepper" rather than Widmanstätten markings, produced the same type of increase in strength level and impact-energy level as found for quenching from the α field.

Titanium-Nickel Phase Diagram

by Harold Margolin, Elmars Ence, and John P. Nielsen

The Ti-Ni phase diagram has been investigated up to 68 pct Ni with iodide titanium base alloys by metallographic, X-ray, and melting point methods, and from 68 to 90 pct Ni by examination of as-cast structures of sponge titanium base alloys.

INVESTIGATION of the nickel-rich portion of the Ti-Ni phase diagram was first reported by Vogel and Wallbaum in 1938.¹ This work was subsequently extended to lower nickel contents by Wallbaum² who indicated the possibility of a eutectic reaction for nickel contents below 38 pct. Long et al.³ studied the titanium-rich portion of the phase diagram and found eutectic and eutectoid reactions below 38 pct Ni. However, the temperature of the eutectic indicated by Long et al. was considerably lower than that suggested by Wallbaum. Long and his coworkers synthesized their alloys by powder metallurgical techniques and encountered oxygen and/or nitrogen contamination. Thus the diagram which was obtained did not represent binary alloying conditions. However from these results the features of the binary diagram were predicted. At Battelle Memorial Institute⁴ the Ti-Ni diagram was investigated up to approximately 11.5 pct Ni with sponge titanium alloys. The range of temperatures used was not sufficient to define the eutectoid temperature or composition.

The data of Wallbaum² and Long et al.³ were of particular interest for the present study, and although the work was originally concerned with the region below 40 pct Ni, the investigation was extended to higher nickel contents in an attempt to resolve the differences between these workers.

Experimental Procedure

Preliminary work on the Ti-Ni system was carried out with duPont Process A sponge titanium alloys to reduce the amount of subsequent work to be done with iodide titanium base alloys. The sponge titanium used contained 99.71 to 99.77 pct Ti, 0.1 pct Fe and 0.005 to 0.009 pct Ni. The iodide titanium obtained from the New Jersey Zinc Co. contained 99.9 to 99.95 pct Ti. Nickel used with sponge titanium was 98.9 pct pure. The high-purity nickel alloyed with iodide titanium was cobalt-free with approximately 0.05 pct C and was obtained through the courtesy of the International Nickel Co.

Discussion on this paper, TP 3468E, may be sent, 2 copies, to AIME by April 1, 1953. Manuscript, Sept. 15, 1952. Los Angeles Meeting, February 1953.

The 15 g sponge titanium charges for melting were prepared by compacting in a die or by placing the weighed portions of nickel and titanium directly into the furnace. Iodide titanium charges were made by drilling holes in the as-received rod and inserting the nickel or by wrapping the nickel in sheet.

Sponge titanium alloys containing from 0.2 to 90 pct Ni and iodide titanium alloys containing 0.2 to 68 pct Ni were prepared by these methods. In addition to these alloys several ½ lb sponge titanium alloys were supplied by the Allegheny Ludlum Co.

The charges were melted in an arc furnace under an argon atmosphere. The procedures used were similar to those reported in the literature^{5,6} and the furnace has been described.⁷ Except for iodide titanium alloys with 40 to 68 pct Ni (see section on copper contamination), each alloy was melted for 1 min, then either turned over or broken before remelting for an additional minute. Currents of 200 to 400 amp were used depending on the melting point of the alloy.

Prior to heat treatment, alloys containing less than 14.5 pct Ni were hot-forged at 750°C. With the exception of alloys in the homogeneity range of the compound TiNi, alloys of higher nickel contents could not be hot-forged. Heat treatment of iodide titanium base alloys was carried out in argon-filled quartz capsules which were broken under water at the conclusion of heat treatment to quench the specimens. Temperatures were controlled to $\pm 5^\circ\text{C}$ and annealing times up to 48 hr were used.

For melting point determination, specimens were placed in carbon crucibles which were in turn encapsulated in argon-filled quartz capsules. The start of melting was determined by rounding of corners and by metallographic examination. Complete melting was considered to have occurred at that temperature at which the specimen assumed the shape of the crucible.

Specimens were prepared for metallographic examination by mechanical polishing or by an electrolytic procedure.⁸ For alloys containing up to 80 pct Ni Remington A etch⁹ (50 pct glycerine, 25 pct HNO₃, 25 pct HF) was used. For higher nickel alloys aqua regia and Carapella's etch (5 g FeCl₃, 2 ml HNO₃, and 99 ml methyl alcohol) were employed.

Specimens to be exposed for powder patterns were prepared by filing, by breaking specimens in a

Fig. 1 (left)—As cast, 70 pct Ni (sponge titanium). Primary $TiNi_3$, eutectic of $TiNi_3$ and $TiNi$, and copper contamination. "A" etch. X75.

Fig. 2 (right)—64 pct Ni (iodide titanium). 4 hr at 950, 20 hr at 900°C, water quenched. $TiNi$, $TiNi_3$ and copper contamination. "A" etch. X500.

die, or by etching annealed specimens. Molybdenum $K\alpha$ and copper $K\alpha$ radiation were employed.

Homogeneity: Nickel alloys could not be obtained in a completely homogeneous state, despite repeated meltings in a number of cases. Analysis of several samples from the same button showed differences which extended up to 1 pct in alloys below 40 pct Ni. Alloys containing greater amounts of nickel showed differences of up to 2 pct Ni, in one case, between top and bottom of the button, the bottom being nickel-rich. The tendency toward increasing composition differences between top and bottom of the button appears to be due to segregation of titanium to the top of the button. This is suggested by the fact that, after the arc was removed, a solidified island appeared at the top of the melt while solidification proceeded from the bottom upward. This behavior was also reflected in the appearance of as-cast buttons containing up to 90 pct Ni. As compared to the bright uniform surfaces of the low nickels, the high-nickel alloys revealed bright tops, superseded by gray frosted areas in the lower regions.

Since specimens from a given button were generally found to contain within 0.5 pct of the nominal composition, these compositions have been used in plotting data for nickel contents above 14.5 pct. For lower nickel contents the actual chemical analyses*

* Analyses by Lucius Pitkin, Inc., New York.

have been used, with a reported accuracy of analysis of ± 0.2 pct of contained nickel.

Copper Contamination: Sponge alloy buttons (15 g) containing above 40 pct Ni after melting revealed a reddish-brown phase which appeared to be concentrated in considerable quantity at the bottom of the button, see Fig. 1. Since the melting hearths of the furnace were generally wet by these alloys, copper contamination was suspected. Analysis of two alloys containing 64.9 and 70 pct Ni showed copper present in the range 0.1 to 0.5 pct. To overcome this difficulty, the size of the charge was reduced from 15 to 5 g and melting time was reduced from two 1-min periods to four 15-sec intervals. Copper contamination was almost entirely eliminated and very few dendrites of the copper phase could be seen, see Fig. 2. Spectrographic analysis of a 65.9 pct Ni button showed copper to be present in amounts of 0.001 pct.

Phase Diagram

The phase diagram for iodide titanium base alloys is shown in Fig. 3 and the diagram to 15 pct Ni for both iodide titanium and sponge titanium alloys is shown in Fig. 4. The use of sponge titanium and impure nickel in these compositions does not appreciably change the iodide titanium base diagram. The constitution diagram of Fig. 3 below approximately 60 pct Ni is quite different from that of Wallbaum,² see Fig. 5. This discrepancy may be at-

Fig. 3 — Ti-Ni phase diagram (iodide titanium-base alloys).

Fig. 4—Partial Ti-Ni phase diagram.

tributed to Wallbaum's use of 95 pct pure titanium and corundum crucibles in which to melt alloys for thermal analysis.

The diagram below the eutectic composition is in good agreement with the prediction of Long et al.³ and the extrapolated data of Battelle⁴ on sponge titanium. A comparison of the data is shown in Table I.

Table I. Comparison of Data

	This Investigation	Long et al. ³	Battelle ⁴ Extrapolated Data
Eutectic temperature	955°±5°C	960°C	
Eutectoid temperature	770°±5°C	765°C	770°C
Maximum β solubility	13 pct Ni	12 pct Ni	
Maximum α solubility	<0.2 pct Ni	<0.5 pct Ni	
Eutectoid composition	6-7 pct Ni	7 pct Ni	7 pct Ni

For higher nickel contents, differences appear in the location of the eutectic point and the compound Ti_2Ni . Based on melting point data and on examination of structures of as-cast alloys, the eutectic composition has been located at 28 to 29 pct rather than at 33 pct Ni. The microstructure of a 33 pct Ni alloy containing primary Ti_2Ni and a eutectic of β and Ti_2Ni is shown in Fig. 6. Long and his colleagues set the γ phase at 41.5 pct Ni "...on the basis of sharp changes in structure between the 39.8 and 44 pct nickel alloys." Laves and Wallbaum¹⁰ suggested that this phase was Ti_3Ni , theoretically containing 38.0 pct Ni, and the d -values for this face-centered cubic compound have been reported by Duwez and Taylor.¹¹ The Duwez and Taylor d -values for this compound have been confirmed in this investigation and examination of microstructures has also located this compound at 38 pct Ni. Although some slight coring was observed in the as-cast alloys of 38 pct Ni, the homogeneity range was found to be quite restricted.

Duweze and Taylor¹¹ have reported that the body-centered cubic compound $TiNi$ decomposes above 800°C, on cooling, into Ti_2Ni and $TiNi_3$. The present authors were unable to obtain evidence for this decomposition in the microstructures of alloys quenched from above and below 800°C (see Fig. 2, characteristic structure for both 750° and 900°C), or in powder patterns obtained from specimens containing 52 and 56 pct Ni annealed at both 750° and 900°C. The a_0 value for $TiNi$, obtained from a 56 pct Ni alloy annealed at 1075°C, is 3.02Å.

The features of the diagram above 68 pct Ni† have

† At the time this work was being prepared for publication additional data on the nickel-rich portion of the diagram was published¹² together with a probable form of the diagram linking the data of Long et al.³ with that of Wallbaum.²

been checked by examination of as-cast, sponge titanium base alloys and several microstructures of as-cast alloys are shown in Figs. 1, 7, and 8. Fig. 7 (90 pct Ni) shows the primary nickel solid solution, a Chinese-script eutectic, the more common eutectic, and the contaminating copper-rich constituent. The presence of the Chinese-script eutectic may be related to the presence of the copper contaminant since the branches of this eutectic are often seen to be emanating from the corners of this phase. If the presence of the Chinese-script eutectic is neglected, then the existence of small amounts of ordinary eutectic may be rationalized from the diagram of Fig. 5.

A typical portion of the as-cast 85 pct Ni alloy is shown in Fig. 8. The white phase is primary $TiNi_3$ and the needle-like structure represents an oriented eutectic according to Vogel and Wallbaum.¹ The presence of primary $TiNi_3$ at a composition somewhat below the eutectic, 16.2 pct Ti, may be due to supercooling. However, Vogel and Wallbaum report uncertainty as to the exact eutectic composition.

In addition to copper contamination, Fig. 1 (70 pct Ni), shows primary $TiNi_3$ and a eutectic of $TiNi$ and $TiNi_3$.

In so far as can be determined from an examination of as-cast microstructures, the data in general confirm the diagram presented by Vogel and Wallbaum.

Observations on the Transformation of β Titanium

The β phase of titanium when alloyed with β stabilizing elements such as molybdenum can transform by nucleation and growth¹³ or by a martensitic reaction.^{13,14} Evidence for both types of β transformation has been obtained in Ti-Ni alloys.

Microstructures of alloys showing transformation of the β phase are shown in Figs. 9 to 15. Figs. 9 to 12 show that increasing nickel contents suppress the transformation of β titanium by nucleation and growth on relatively slow cooling. The transformation of β titanium can be entirely suppressed on quenching when this phase contains approximately 8 pct Ni.

Fig. 13 is a micrograph of an iodide titanium-5 pct Ni alloy slowly cooled from just above the eutectoid temperature. The structure consists of isothermal

Fig. 15—14.5 pct Ni (iodide titanium). 20 hr at 950°C, water quenched. Retained β , Ti_2Ni and eutectoid of α and Ti_2Ni . "A" etch. X150.

α and transformed plus retained β . The fine transformation needles within the β grains are parallel to the platelets of isothermal α , thus suggesting that transformation of β below the eutectoid temperature occurred by the same mechanism governing the formation of α in the $\alpha + \beta$ field.

Pearlite decomposition has been observed in specimens rapidly cooled from the $\alpha + \beta$ field to 100°C below the eutectoid temperature. This behavior suggests that during the slow cooling below the eutectoid temperature the partial decomposition into α observed in Fig. 12 caused sufficient enrichment of the β phase to stabilize it. Since approximately 8 pct Ni is required to retain β on quenching, the retained β of this 5 pct alloy must contain at least this quantity of nickel.

Both α and Ti_2Ni can stimulate the transformation of β titanium. In the case of α , slow cooling in the $\alpha + \beta$ field develops sharp projections as shown in Fig. 14. In areas adjacent to these α projections transformation occurs most readily and is particularly evident in alloys in which limited transformation takes place. Transformation in areas adjacent to Ti_2Ni is shown in Fig. 15. At higher magnifications these areas can be resolved into a pearlitic arrangement of $\alpha + Ti_2Ni$.

Summary

The Ti-Ni phase diagram has been investigated with alloys of iodide titanium and high-purity nickel up to 68 pct Ni by metallographic, melting point, and X-ray methods and up to 90 pct Ni by examination of as-cast structures of sponge titanium base alloys. The Ti-Ni phase diagram may be summarized as follows:

1—Eutectoid decomposition of β containing 6 to 7

pct Ni into α (<0.2 pct Ni) and Ti_2Ni (38 pct Ni) at $770^\circ \pm 5^\circ C$. 2—Eutectic solidification of liquid containing 28 to 29 pct Ni into β (13 pct Ni) and Ti_2Ni at $955^\circ \pm 5^\circ C$. 3—Peritectic formation of Ti_2Ni from liquid (~ 37.5 pct Ni) and $TiNi$ (~ 53 pct) at approximately $1015^\circ C$. 4—Eutectic solidification of liquid (~ 65 pct Ni) into $TiNi$ (~ 59 pct Ni) and $TiNi_3$ (78.6 pct Ni) at approximately $1110^\circ C$. 5—Eutectic solidification of liquid to form $TiNi_3 + \gamma$.

The β phase may transform by a nucleation and growth process or by a martensitic reaction. The transformation of β may be stimulated in the presence of α or Ti_2Ni or may be suppressed on water quenching alloys containing 8 pct Ni or more.

Titanium-Carbon Phase Diagram

by Irving Cadoff and John P. Nielsen

The Ti-C phase diagram exhibits a peritectic point at 1750°C and 0.8 pct C, and a peritectoid point at 920°C and 0.48 pct C. The maximum solubility of carbon in α titanium is 0.48 pct. The δ region containing the TiC compound (20 pct C) extends to 11 pct C at the peritectic temperature.

THE interest in the Ti-C alloy system stems from the fact that carbon occurs as an impurity in titanium alloys when graphite electrodes or graphite crucibles are used in their melting. Since titanium-base alloys are still in the development stage, some virtue may be found in carbon addition to titanium. The TiC compound is currently emerging as an important powder metallurgy base constituent similar to the WC compound.

Ehrlich¹ identified the phases and structures present in the Ti-C system. The peritectoid region of the phase diagram was investigated by Jaffee et al.² A preliminary diagram based on theoretical considerations was proposed at the outset of this research.³ The TiC compound has been investigated extensively and has been reported on in a large number of papers.

Experimental Procedure

Arc-melted alloys of 24 compositions in the range 0 to 20 wt pct C were investigated using metallography, X-ray diffraction, and, for the liquidus and solidus regions, incipient and complete melting.

All alloys were prepared from iodide titanium (New Jersey Zinc Co., 99.95 pct Ti minimum) and spectroscopic grade carbon (National Carbon Co.). To prevent carbon spattering during arc melting the carbon was encapsulated in titanium. For alloys containing less than 1 pct C the powder was inserted

This paper is based on a thesis by I. Cadoff submitted in partial fulfillment of requirements for the degree of Doctor of Engineering Science to the Graduate Division, College of Engineering, New York University.

into a capsule formed by drilling a hole in the as-received rod. For higher compositions, capsules were formed from titanium sheet.

Arc Melting: The charges were melted in the copper-hearth cold electrode furnace shown in Fig. 1. This furnace is similar in principle to the all-metal unit adapted for titanium melting at Battelle Memorial Institute.⁴ The transparent pyrex walls giving unlimited visibility during operation and the multiple-

hearth base allowing for consolidation of six charges per run were modifications developed for the furnace used in the present investigation.

Charges, weighing 15 g, were melted three times, 1 min for each melting, the buttons being turned over between melts. For compositions above 4 pct C the buttons tended to be inhomogeneous after the three melts, and additional meltings were required. Increased melting time was necessary with carbon contents above 4 pct. Direct current power of 150 to 300 amp at arc voltages of 20 to 30 v were sufficient to melt alloys containing less than 7 pct C. Raising the current beyond 300 amp for the higher content alloys caused an excessive weight loss from spattering and vaporization. The spattering and vaporization were significantly reduced by decreasing the current to 200 amp and increasing the melting time to 30 to 45 min. These alloys, because of the high heats developed during melting, could not be successfully melted in the pyrex wall furnace and therefore were melted in an all-metal unit.

Contamination on melting was minimized by evacuating the furnace to less than 10 microns pressure, flushing with high-purity argon several times (99.9+ pct argon supplied by Matheson Chemical Co., N. J.), and melting under a 20 cm partial initial pressure of argon. The leak rate of the furnace chamber was kept below 60 microns per hour. Vickers hardness was used to determine the degree of contamination and 15 g control buttons melted for 1 min increased less than 10 Vickers per melting.

Heat Treatment: To aid in attaining equilibrium during heat treatment, specimens were cold or hot-rolled prior to heat treatment wherever possible. Specimens were heat-treated in sealed quartz capsules for temperatures up to 1400°C. Prior to sealing, the capsules were evacuated to a pressure less than 1 micron and then filled with argon to a pressure corresponding to 1 atm for the heat-treatment temperature. The specimens were wrapped in titanium sheet before capsulating to prevent a specimen-quartz contact. A tabulation of heat-treatment time used at the various temperatures is given in Table I. Where time ranges are indicated, the longer times were used for the higher carbon content alloys. Temperatures were controlled to at least $\pm 3^\circ\text{C}$ with closer control used when necessary. The specimens were quenched by crushing the quartz capsules under water.

Solidus and Liquidus Regions: The unit used to determine the melting range is shown in Fig. 2. The specimen, about $\frac{1}{8}$ in. cube, is placed in the heater boat, as shown. The heater boat, either molybdenum or tantalum, is heated by its own electrical resistance with currents up to 200 to 300 amp, the specimens coming to heat rapidly. Incipient melting was identified by the occurrence of a rounding of corners. Complete melting was assumed to have oc-

Fig. 2—Melting point determination unit.

curred when the solid specimen appeared to collapse and run along the trough of the heater. Calibration measurements indicated that black-body conditions were attained. Accuracy of a determination was estimated as $\pm 25^\circ\text{C}$. The sight tube may be adjusted by means of the magnets to sight directly on the specimen. The optical pyrometer is fitted with a microscope lens so that the specimen may be observed closely. The unit is operated under vacuum to minimize contamination.

This unit was also used for heat treatments above 1400°C, i.e., beyond the quartz capsule range. A quench was obtained in this apparatus by virtue of the water-cooled electrode leads, which cooled the specimens in less than 2 sec.

Metallography: Metallographic specimens were prepared using an electropolishing technique.⁵ Principal etchants used were Remington A⁶ and cyanide stain,⁷ the latter being useful in identification of carbides.

X-Ray Diffraction: X-ray diffraction patterns were taken with a powder camera (radius of 57.3 mm) using $\text{CuK}\alpha$ radiation. For phase identification powder specimens were prepared by filing or crushing to 230 mesh, the filed powders being subsequently annealed. Lattice parameter measurements revealed that the heat-treated powders had been contaminated to the extent that the data obtained were useless. To overcome this, specimens were etched with HF to a wire diameter of 0.015 in. To eliminate spottiness due to grain size and preferred orientation, specimens were cold-rolled and recrystallized prior to etching. The recrystallization was controlled so that the grain size corresponded to ASTM No. 5 or smaller. The line positions were determined from averages of three measurements and the parameters were calculated using Cohen's method of least squares.⁸

Chemical Analysis: The weight loss of titanium during melting for alloys containing less than 7 pct C was negligible, permitting the use of nominal compositions in this range. Chemical analyses* justified

this procedure. Above 7 pct C the weight loss was excessive and the compositions used are those obtained from chemical analyses.

Results and Discussion

The Ti-C phase diagram in the range 0 to 20 pct C is presented in Figs. 3 to 5.

The region of the α and β solvus lines, the α plus

Fig. 4—Iodide titanium-carbon phase diagram detail from Fig. 3.

β field, and the peritectoid point is shown in Fig. 4. The solubility of carbon in α titanium is at a maximum at the peritectoid point, 0.48 ± 0.02 pct C, and decreases with decreasing temperature. In a series of homogenizations designed to bracket the peritectoid reaction temperature, a three-phase structure, Fig. 6, was obtained which confirmed this temperature at $920^\circ \pm 3^\circ\text{C}$. Annealing at 925° and 915°C resulted in structures of δ plus transformed β and α plus transformed β , respectively. The peritectoid point was bracketed between the 0.45 pct C alloy and at 915°C , exhibiting α plus transformed β , and the 0.50 pct C alloy at 915°C , exhibiting α plus δ . The solubility of carbon in β titanium at 920°C is about 0.15 pct C and increases with increasing temperature to about 0.8 pct C at the peritectic temperature, Fig. 5. Ehrlich¹ reported carbon solubility in titanium as high as 2.0 pct C. This high solubility may be attributed to the probable presence of oxygen and nitrogen in his alloys, which contamination increases the solubility of carbon in titanium.⁹ Jaffee, et al.,² using iodide titanium for their alloys, found carbon solubility in both α and β titanium less than 0.45 and 0.1 pct C, respectively.

Fig. 5 is a detail showing the delineation of the phase boundaries in the region of the peritectic reaction. The presence of a peritectic was suspected on the basis of as-cast alloys in which primary δ was found in alloys of carbon content as low as 0.2 pct, Fig. 7. That carbon raised the melting point was further substantiated by relative liquidus temperature determinations of carbon alloys below 0.5 pct. By placing two specimens of slightly different

Fig. 5—Iodide titanium-carbon phase diagram detail from Fig. 3.

carbon content on the heater boat of the solidus-liquidus determination apparatus described above and heating until one specimen melted, it was found that the specimen of lower carbon content always melted first. This procedure was necessary since the difference in liquidus temperatures for two specimens of carbon content within 0.1 pct of each other was smaller than the precision of a temperature measurement.

Measurements of incipient melting points indicated that the peritectic temperature was below 1760°C . Assuming a peritectic reaction, the peritectic horizontal would therefore have to be above 1725°C , the melting point of iodide titanium.¹⁰ An absolute measurement of the peritectic temperature on the basis of incipient melting observations within this 1760° to 1725°C range was limited by the instrument, the accuracy of measurement of which was

Fig. 13—Effect of carbon on the lattice parameters of iodide titanium.

estimated at $\pm 25^\circ\text{C}$. However, a study of as-cast microstructures indicated that the solubility of carbon in liquid titanium is just under 0.2 pct C at the peritectic temperature. Using this information, the peritectic line was drawn so that it intersected the previously established liquidus line at just under 0.2 pct C, locating the peritectic at 1750°C . It was estimated that the probable error of this temperature value is less than $\pm 20^\circ\text{C}$.

The liquid plus δ/δ boundary (Fig. 3) was confirmed by microstructural examination of the 11.2 pct C alloy quenched from the liquid plus δ region, Fig. 8.

No evidence of an intermediate phase could be found in any of the temperature ranges above 600°C . An alloy corresponding to Ti_3C was treated at 500°C for two weeks with no evidence of compound formation. As shown in Figs. 9 to 12, the amount of δ in the two-phase regions, α plus δ , and β plus δ , increases with increasing carbon content until the δ field is reached.

The phase within the δ in Figs. 10 and 11 is either α or transformed β which has precipitated as a result of the decreasing solubility in TiC with decreasing temperature. It is interesting to note that the surface energy of the δ in contact with the Ti-C liquid solution is significantly different from the surface energy of this phase in contact with the β phase of the same carbon content. In the first case the liquid serves as the matrix with δ as the included phase; and in the second case the δ tends to serve as the matrix for the β , as is indicated by the β precipitates in the δ phase and by the sharp angles the δ constituents have developed at grain boundaries of β , Fig. 10. Fig. 11 gives the appearance of the liquid serving as matrix around the δ phase for a different composition alloy.

The δ phase region extends to 11 pct C at the peritectic temperature and narrows down moderately with decreasing temperature. The melting point of TiC was taken from reported values.¹¹ The δ phase gave a face-centered cubic X-ray diffraction pattern consistent with Ehrlich's¹ report that the compound was a NaCl type. Ehrlich, however, found δ to exist for carbon contents as low as 7 pct. This discrepancy

might be explained by the probable presence of contamination in early titanium work.

Lattice parameter measurements were made on a series of alloys to determine the effect of carbon on the parameters of α titanium and to determine the position of the α solvus. The lattice parameter data of a series of single-phase quenched alloys are presented in Fig. 13. The parameters of iodide titanium agree with those reported by Clark.¹² The effect of carbon on expanding the lattice is more marked than that of oxygen or nitrogen,¹² particularly for the a parameter.

For an independent determination of the α solvus, the α phase parameters of α plus δ alloys, heat treated in the α plus δ region at four different temperatures, were determined. There was good agreement between the X-ray determined α solvus and the α solvus determined microstructurally. The results are presented in Fig. 4.

Summary

Carbon raises the allotropic transformation temperature of titanium from 882°C to 920°C . A peritectoid reaction, $\beta + \delta \rightarrow \alpha$, takes place at 920°C and 0.48 pct C, the maximum solubility of carbon in α titanium. The solubility of carbon in β titanium increases from 0.15 pct at 920°C to a maximum of 0.8 pct at 1750°C . A peritectic reaction, liquid + $\delta \rightarrow \beta$, occurs at 0.8 pct C and 1750°C . The liquidus line rises continuously from the peritectic temperature, with increasing carbon content, to the TiC melting point. Carbon in iodide titanium increases both the c and a parameters of the α form.

Acknowledgments

The authors wish to thank H. Margolin, A. E. Palty, and the staff of the Metallurgy Laboratory at New York University for their assistance in this research. They also wish to thank the Ordnance Corps, Watertown Arsenal, for permission to publish this work, and L. D. Jaffe of the Watertown Arsenal Laboratory for his helpful criticism and comments. Constitution of Titanium-Rich Ti-Cr-Al Alloys

At 1800° and 1400°F

by Jack L. Taylor and Pol Duwez

The phase boundaries in the ternary system Ti-Cr-Al have been established at 1800° and 1400°F for alloys containing more than 60 pct Ti. The martensite transformation temperature has been measured for the titanium-rich alloys.

THE studies of binary alloys of titanium with the transition elements which have been published so far¹⁻⁹ indicate clearly that the solubility of these elements is always much greater in the high temperature body-centered cubic form of titanium (β phase) than in the low temperature hexagonal form. In this category of alloying elements are iron, nickel, chromium, manganese, vanadium, molybdenum, tungsten, columbium, and tantalum. Although studies of the nontransition elements have been rather limited, early work on titanium binary alloys¹⁰ has shown that most of them were not very soluble in the α form, with the exception of aluminum, for which the solubility in α is about 25 pct.^{11, 12} In addition to this large solubility in α , aluminum is also soluble in β titanium to the extent of about 35 pct and the transformation temperature from β to α is raised with aluminum content. This effect is also typical of aluminum, in contrast with that found for the transition elements which lower the β to α transformation temperature. Therefore, it may be anticipated that ternary titanium alloys

with aluminum and any one of the transition elements will constitute a class of ternary alloys having characteristic features absent in alloys involving two transition elements.

Chromium was chosen as a typical transition element for the present study because ternary alloys of Ti-Al-Cr commercially produced have been found to possess very interesting physical properties (MST-3 pct Al-5 pct Cr of Mallory-Sharon).¹³

Binary Systems

The binary systems Ti-Al and Ti-Cr have been established recently by several investigators. The data used in this investigation were taken from the complete diagram of Bumps, Kessler, and Hansen.¹¹ This diagram agrees quite well with earlier investigations.¹² For the Ti-Cr system, the phase boundaries at 1800° and 1400°F were taken from refs. 6 and 7. The binary system Cr-Al has been studied recently by Bradley.¹⁴ This system is rather complex and contains not less than seven intermediate phases. The present study was limited to the titanium corner of the ternary system (less than a total of 40 pct Cr plus Al) and none of the phases present in the Cr-Al binary alloys were found in the ternary alloys investigated.

Experimental Technique

Microscopic observation and X-ray diffraction measurements were used to identify phases and de-

Fig. 1—Partial ternary diagram showing composition of alloys in weight percent at 1800°F.

termine phase boundaries. A total of 130 alloys were prepared by melting in a helium arc furnace on a water-cooled copper plate. The furnace is essentially the same as that described previously.¹⁵ The alloy compositions are shown in Figs. 1 and 2.

The titanium used in this investigation, refined by the iodide process, was received from the New Jersey Zinc Co. According to the manufacturer, a typical analysis of this product is: Mn, 0.0065 pct; Fe, 0.0022; Cu, 0.0015; and Pb, 0.0042. The Vickers hardness number (10 kg load) of the iodide titanium as-received varies between 55 and 80. The chromium powder, obtained from Charles Hardy, Inc., has the following spectroscopic analysis: Na, 0.1 pct; Ca, 0.05; and traces of copper, manganese, silicon, cobalt, and magnesium. The electrolytic chromium powder was first pressed and then sintered in pure dry hydrogen at 2500°F. The aluminum, which was furnished through the courtesy of the Aluminum Company of America, is reported to be 99.99 pct pure.

The three metals were melted together from

Fig. 2—Partial ternary diagram showing composition of alloys in weight percent at 1400°F.

small pieces to make a 3 or 4 g sample. The homogeneity of the samples was checked microscopically before further work. The prepared composition was accepted if weight losses during melting were less than 1 pct. All samples were sealed in evacuated quartz tubes (10^{-4} mm Hg or better) and homogenized for 4 hr at 1800°F. They were then quenched by breaking the tube under water. Filings from each sample were sealed in quartz vials and quenched in liquid argon after 2 min at 1800°F. The samples for the 1400°F study received the same homogenization treatment as those at 1800°F plus 10 days at 1400°F. Quenching from 1400°F was accomplished by immersing the quartz tubes in water. Filings from these samples were annealed for 4 hr and quenched under water without tube breakage.

Fig. 3—Phase boundaries in partial ternary Ti-Cr-Al diagram at 1800°F.

Diffraction patterns of the filings were taken on a 14.32 cm camera using Cu K α radiation as filtered through nickel foil. Measurements were taken from film mounted asymmetrically in the camera. This mounting automatically compensates for film shrinkage.

The alloy specimens, mounted in lucite, were polished through a series of successively finer papers and given a final polish on a cloth lap with 2 micron diamond paste. The titanium etching solution consisted of one part nitric acid, one part hydrofluoric acid, and two parts glycerin. The microscopic studies were made at 250 diameters in most cases.

Phase Boundaries at 1800°F

The isothermal ternary phase diagram for Ti-Cr-Al alloys at 1800°F is shown in Fig. 3. The isoparametric lines in the β solid solution region are given in kX units.

The boundary between the β and the β plus α region was established mostly on the basis of microscopic observation, since the beginning of α precipitation can be clearly detected. It is believed that the boundary along alloys No. 32, 25, 10, 11, and 12 between β and α plus β is accurate within 1 pct. The isoparametric lines were based on parameters taken from at least three resolved doublets. Within the β field, there is an area near the titanium apex where β is not retained after quenching. Microscopic ob-

servation was used to differentiate a pure β retained structure from a structure containing some α' (supersaturated α resulting from a martensite type transformation of β). The temperature at which the martensite transformation takes place has also been measured and the results are described in a subsequent section.

The boundary between the β and the β plus γ fields has not been determined with the accuracy of the β to α plus β boundary. The sluggishness of solid state reactions in this composition range adds an element of uncertainty as to correct sampling by filing for X-ray. As for the β boundary near the apex of the ternary region, possible lack of equilibrium, incorrect proportions in X-ray sampling, and the difficulty of detecting a third phase under the microscope are unfavorable factors introducing uncertainties in locating this boundary. The alloys shown by only a dot on the diagram of Fig. 1 are those for which phase identification was most uncertain.

The boundary between the α and the α plus β fields was determined from X-ray measurements. It is interesting to note that the width of the α ternary solid solution is quite narrow. This result demonstrates the strong tendency of chromium toward stabilizing the β phase in titanium. The X-ray patterns in the α plus β field did not have clearly resolved doublets and consequently the tie lines were not determined in the two-phase region.

The boundary between the α plus δ and the α plus β plus δ fields was determined quite accurately to lie between alloys No. 76 and 127. Only one alloy (No. 105) was identified as containing the three phases α , β , and δ . The three-phase region was traced in such a manner that the apexes of the triangle are located on the boundaries of the three one-phase regions.

Phase Boundaries at 1400°F

The phase boundaries at 1400°F are shown in Fig. 4. The limit of solubility of aluminum in the ternary β phase appeared to be of the order of 1 pct, as shown by alloy No. 33. Subsequent findings indicated a more complicated distribution of phases than was expected from considering Fig. 3 at 1800°F.

Fig. 4—Phase boundaries in partial ternary Ti-Cr-Al diagram at 1400°F. (The phase boundaries for alloys containing less than 70 pct Ti are only tentative.)

Fig. 5—Composition of titanium-rich alloys and the temperature at which the β phase transforms to α' .

The β phase reappears at alloy No. 20, containing 20 pct each of chromium and aluminum. This result indicated that the β region is split in two at 1400°F.

X-ray diffraction results were the deciding factor in determining boundaries between two and three-phase regions. Assuming TiCr_2 to be the stoichiometric composition, straight lines drawn to the other one-phase regions defined two other split fields, namely α plus β and α plus β plus γ . The X-ray results agree quite well with these requirements, with the exception of those alloys shown as dots (No. 77 and 83).

The apex of the ternary field containing α plus β plus δ , which touches the β region, is beyond the compositions studied in this paper. However, alloys No. 70, 75, 104, and 80 gave fair accuracy in locating the boundary between the α plus β and the α plus β plus δ fields. Similarly, the α plus δ field was defined by alloys No. 70, 128, and 102. The β plus δ boundary location was the least accurate because of the uncertainty in alloys No. 87, 110, 106, and 82, shown as dots.

Martensite Transformation Temperature

A series of alloys whose compositions are shown in the ternary diagram of Fig. 5 were used for the measurements of the temperature at which the β phase transforms, at least partially, to α' . The technique used for the determination of the transformation temperature during rapid cooling was that described by Greninger in his study of martensite in carbon steels.¹⁶ The same technique has been used more recently for the study of some titanium binary systems.^{9, 15, 17} The specimens were about 0.020 in. thick and 1/16 in. square. Chromel-alumel wires, 0.005 in. in diameter, were placed between the two pieces and the assembly spot welded. The specimens were heated by means of a molybdenum coil in vacuum and rapidly cooled by a helium jet. The temperature was recorded on a rotating drum-type oscillograph. The break in the cooling curve due to the heat released by the transformation was quite easy to locate with an accuracy of $\pm 5^\circ\text{C}$. However, the scatter between results obtained on different samples of the same alloy was generally greater than $\pm 5^\circ\text{C}$.

For each alloy at least five measurements were made with rates of cooling in the range of 200° to 600°C per sec (390° to 1110°F per sec). Within this

Fig. 6—Isothermal lines showing the compositions at which the β to α' transformation occurs for a given temperature.

range it was found that, as in the case of binary alloys,¹⁷ the transformation temperature was independent of the rate of cooling.

The results of temperature measurements on various ternary alloys are indicated on Fig. 5. The transformation temperatures for the binary Ti-Cr alloys were taken from a previous study.¹⁷ For the Ti-Al binary alloys, unpublished results of measurements made in this laboratory indicate that the Ms temperature increases regularly with aluminum content. In the range from 0 to 5 pct Al, which is the composition corresponding to the boundary of the β phase at 892°C (1635°F), the martensite transformation temperature increases from 882°C (1620°F) to about 940°C (1725°F).

As mentioned in previous studies, the relative amount of β transforming into α' decreases also with increasing concentration; and hence, the thermal arrest becomes weaker and difficult to observe. It is, therefore, not possible, with the sensitivity of the present method of measurement, to establish the Ms curves below approximately 300°C (570°F). Microscopic observation is probably the most reliable method for determining the concentration at which the change occurs from a β plus α' needle structure into a pure β structure. The boundary limiting the compositions for which β is retained, as shown in Fig. 6, is based on microscopic observation. By plotting the martensite temperature vs chromium content for various constant aluminum contents, it was possible to determine compositions having an Ms temperature of 800°, 700°, 600°, and 500°C (1470°, 1290°, 1110°, and 930°F). These plots lead to the tracing of the isothermal lines of Fig. 6, which represent the compositions at which the β to α' transformation takes place at a given temperature. These isothermal lines are roughly parallel to the Ti-Al side of the ternary diagram and hence the amount of chromium in the ternary alloy practically determines the temperature at which the transformation takes place. This result is of course a consequence of the fact that the addition of aluminum to titanium has only a relatively small influence in raising the martensite transformation temperature.

Conclusions

The phase boundaries of the Ti-Cr-Al ternary system have been determined at 1800°F (980°C) and at 1400°F (760°C) in the portion of the diagram

extending from the titanium corner down to compositions containing 60 pct Ti. At 1800°F the β field covers a large portion of the diagram. Within this β field the boundary limiting the field of compositions for which the β phase transforms into the α' supersaturated solid solution has been established. The temperature at which the β to α' martensite transformation takes place has also been determined for the titanium-rich alloys.

Mechanism of Plastic Flow in Titanium —

Determination of Slip and Twinning Elements

by F. D. Rosi, C. A. Dube, and B. H. Alexander

The slip and twinning planes have been determined in deformed crystals of titanium by an X-ray method of analysis. The slip planes are of the type $\{10\bar{1}0\}$ and $\{10\bar{1}1\}$, while the twinning planes are of the type $\{10\bar{1}2\}$, $\{11\bar{2}1\}$, and $\{11\bar{2}2\}$. In the case of the predominant $\{10\bar{1}0\}$ slip, a type I digonal axis of indices $\langle 1120 \rangle$ was the effective slip direction. Microscopic observations on the appearance of the three twin types disclosed a distinct difference in their shapes, and an attempt was made to correlate this difference with the amount of twinning shear. The slip mechanism was discussed on the basis of the difference in c/a ratios for the common hexagonal close-packed metals.

IT is a general rule that slip in metals occurs most easily on the planes of greatest atomic density and of the largest interplanar spacing, and that the direction of slip is a close-packed direction. Thus, of the hexagonal close-packed metals which have been investigated by the German school in the decade 1925 to 1935 (cadmium, zinc, and magnesium), it has been found that slip occurs on the basal plane (0001) and in a $\langle 11\bar{2}0 \rangle$ direction.¹ In the case of magnesium above 225°C, slip occurs on a first-order pyramidal plane $\{10\bar{1}1\}$ as well as on the basal plane.² The hexagonal metals, moreover, deform in part by twinning, and, again with the exception of magnesium at elevated temperatures, the twinning plane has always been reported to be a second-order pyramidal plane $\{10\bar{1}2\}$.¹

In view of this consistency in the plastic behavior of these metals, it has been supposed that the same slip and twinning elements would be operative in the other important hexagonal close-packed metals (titanium, zirconium, and beryllium), although there are some reasons why this may not be so. Referring to the tabulation in Table I of the axial ratios of the important metals in this structural class, it may be seen that they can be categorized into three distinct groups depending on the value of their c/a ratios. In the first group are cadmium and zinc with large positive deviations from the ideal ratio for closest packing. This expansion in the direction of the c -axis would be such as to accentuate the basal plane as the slip plane, because it increases the interplanar spacing. The second group includes cobalt and magnesium, which closely approximate the ideal ratio. In the third group are zirconium, titanium, and beryllium whose axial ratios are decidedly less than the ideal. The lattice of the elements in this group is compressed along

Table I. Grouping of Important Hexagonal Close-Packed Metals According to Their c/a Ratios

Metal	c/a Ratio	Pct Deviation from Ideal	Group
Cd	1.886	+15.5	I
Zn	1.856	+13.6	I
Ideal c.p.h.	1.633	0	
Mg	1.624	-0.55	II
Co	1.624	-0.55	II
Zr	1.589	-2.69	III
Ti	1.587	-2.81	III
Be	1.568	-3.98	III

the c -axis which, in effect, tends to make the basal plane less favorable for slip inasmuch as it reduces the interplanar spacing and the atomic density of this plane. Thus, for metals in the third group, it may be said that there is a certain indefiniteness about the glide plane, in that planes other than the basal plane may be expected to operate.

The fact that magnesium begins to exhibit planes other than the normal slip and twinning planes at elevated temperatures may indicate that this behavior will become more pronounced in metals of lower axial ratios. For this reason it might be expected that the slip and twinning behavior of zirconium, titanium, and beryllium would be different from that found in cadmium and zinc. One indication that there is a difference is reflected in the recent work which has been done on the deformation textures of these metals.³⁻⁶ As will be shown later, there is a significant difference between the rolling textures of cadmium, zinc, and magnesium on the one hand, and zirconium, titanium, and beryllium on the other, and this difference suggests that the mechanism of plastic flow is not the same in these two groups of metals.

From these considerations, therefore, it may be seen that there are good reasons why it cannot be concluded that titanium will have the same crystallographic elements of slip and twinning as those exhibited by zinc and cadmium. For the complete determination of these elements it would be most advantageous to have single crystals. However, much valuable information can be obtained by using coarse grained polycrystalline specimens, provided the grains are sufficiently large to permit X-ray

orientation determinations and accurate metallographic examination. In the absence of single crystals, the present study was undertaken using very coarse grains in order to gather as much information as possible concerning the deformation characteristics of titanium.

Production of Coarse Crystals

The titanium used in these experiments was a duPont sponge, which had the following analysis: 99.77 pct Ti, 0.10 pct Fe, 0.009 pct N, 0.05 to 0.08 pct O. This sponge was arc melted in an argon atmosphere into slugs which weighed approximately 25 g each. These slugs were then cold rolled approximately 90 pct to a sheet thickness of 0.05 in. Since the strain-anneal technique was adopted for obtaining the coarse grains, the rolled sheets were annealed to produce a relatively fine, equiaxed and uniform grain size (grain diameter equals 0.04 mm) which is a prerequisite for this method of crystal production.

In order to ascertain the value of critical strain for this material, strips about 0.25x2 in. were cut from the annealed sheets and strained by bending about different radii. The radius of the bend was adjusted to give deformations in the outer fibers of about 1, 2, and 3 pct. The bent strips were then heated in a vacuum at a rate of approximately 150°C per day from 400°C to 840°C, followed by a final anneal at 840°C for two days. The results of these exploratory strain-anneal treatments are

Fig. 2—Coarse grains in titanium produced by controlled recrystallization. X2. Area reduced approximately 20 pct for reproduction.

shown in Fig. 1, from which it may be seen that the optimum deformation for maximum grain size in this material is in the vicinity of 1 pct for a bending type of stress. Consequently, this value of strain was used in a number of specimens to produce two-dimensional growth of grains, which frequently traversed the width of the specimen and facilitated accurate X-ray orientation determinations. For a simple tension type of stress the critical strain was found to be 1.5 pct, and best results were obtained when the annealed structure, prior to the critical strain, consisted of uniform, coarse grains which exhibited a rather strong preferred orientation. A typical example of a coarse grained tensile specimen, with grains averaging 3 to 6 mm in length, is shown in Fig. 2.

Preparation of the surface of these specimens for optical microscopy consisted of mechanically polish-

Fig. 3—Nature of slip and twinning in titanium. X100. Area reduced approximately 40 pct for reproduction.

ing through 4/0 metallographic emery paper and then etching with a dilute solution of hydrofluoric acid to remove the cold-worked layer resulting from this mechanical treatment. A final polish on silk and gamal cloths followed again by a light etch produced a satisfactory surface. An annealing treatment in vacuum at a temperature of 850°C for several days indicated that such surfaces were essentially stress-free.

Appearance of Slip Bands and Twins

Coarse grained specimens of titanium, which have been deformed several percent either by extension, bending, or compression in a vise, show well-marked slip bands and twins, as exemplified by Figs. 3 and 4. It is readily apparent from Fig. 3 that the slip bands are rather fine and straight, and show a reasonable regularity in their spacing, which is approximately 1.5×10^{-2} mm. A particularly notable feature of this deformed crystal is the appearance of five distinct slip systems in addition to the twins. Presupposing the presence of basal slip, this observation establishes at once the existence of at least another slip plane in the deformation of titanium at room temperature, since basal slip can only account for one parallel set of slip traces.

Typical appearance of twins in deformed crystals is shown in Fig. 4. These coarse grains were re-polished and etched after deformation for the purpose of removing the slip bands. It may be seen that the twins appear either very thick, similar to those found in zinc⁷ and magnesium,⁸ or as narrow lamellae much like the Neumann bands characteristic of

twinning in iron.⁹ This latter form of twins is remarkably illustrated in the stepped twin formation of Fig. 4c. As in the case of slip in Fig. 3, close examination of these micrographs reveals at least seven different sets of twin traces. This suggests that twinning in titanium occurs on at least two different crystallographic planes, since twinning on the conventional $\{10\bar{1}2\}$ planes can only account for six of these traces.

It appears, therefore, from these qualitative observations on the appearance of slip bands and twins in large crystals of titanium that the mechanism of plastic flow in this metal at room temperature is much more complex than that found in the hexagonal close-packed metals, zinc, cadmium, and magnesium.

Determination of Slip and Twinning Elements

Experimental Methods: The method of identification of the slip and twinning planes was based on the use of a stereographic plot of a back-reflection Laue photograph describing the region where slip and twinning were observed. Identification resulted from the location in these plots of the poles of the planes responsible for the slip and twinning traces on the surface of the specimen. An example of the application of this method is shown in Fig. 5. The spots from a back-reflection Laue photograph of the crystal, Fig. 5b, (with the incident beam perpendicular to the specimen surface) were transferred to the stereographic diagram, Fig. 5a, on which were plotted the poles of the important planes of low indices. The normal to all visible slip traces (solid lines) and twinning traces (dashed lines) were then shown on the stereographic diagram as great circles passing through the center of the projection. The poles intersected by these great circles identify the slip and twinning planes. In order to distinguish clearly between the slip and twin markings, the specimen, after deformation, was carefully repolished and etched to remove the slip bands, as shown

a—Deformed crystal of titanium repolished and heavily etched to remove slip bands. X50.

b—Diagram of traces of twinning planes.

c—Twin markings on mutually perpendicular surfaces, A (top) and B (bottom).

Fig. 6—Two-surface method of analysis for determining twinning plane. Twins are of the type $\{11\bar{2}1\}$.

in Fig. 5c. In using this technique of crystallographic analysis, it is readily apparent that great care must be exercised with regard to reference marks describing the relation of the X-ray beam to the general outline of the specimen surface.

In a number of cases the normals to the twin traces intersected two poles on the stereographic diagram, and this necessitated a two-surface method of analysis to distinguish which pole was responsible for the trace. This technique, illustrated in Fig. 6, involved the preparation of two surfaces at right angles, such that the twin traces in a given crystal could be clearly followed from one surface around the edge to the other surface, Fig. 6c.

In this particular crystal, Fig. 6a, the normal to the long twin traces on the surface A intersected two poles on the stereographic projection describing this surface. By simply rotating this projection 90° on to the surface B, and again drawing the normal to the traces (Fig. 6b), it is relatively easy to distinguish which of the two poles represents the plane responsible for the traces. Since this two-surface

solution is more rigorous in the determination of the slip and twinning planes, it was adopted, whenever possible, to verify the determinations made by the single surface X-ray technique demonstrated in Fig. 5. The surface preparation shown in Fig. 6 also permits a confirmation of these results by the two-surface method which involves measurement of angles of the twin traces with respect to a crystallographically known system of coordinates.¹⁰

Slip and Twinning Elements: More than 40 stereographic analyses of Laue photographs of deformed crystals were made, and the results of these analyses show that two slip planes and three twinning planes are operative in the plastic deformation of these crystals at room temperature. The slip planes are of the type $\{10\bar{1}0\}$ and $\{10\bar{1}1\}$ while the twinning planes are of the type $\{10\bar{1}2\}$, $\{11\bar{2}1\}$, and $\{11\bar{2}2\}$. In the case of slip, the prismatic type $\{10\bar{1}0\}$ is by far the more predominant. It occurred in all but one of the deformed crystals and in this single exception deformation took place solely by twinning. On the other hand, first-order pyramidal slip $\{10\bar{1}1\}$ was observed only in those crystals which exhibited a complex slip process, in that all three prismatic systems were operative. Typical appearance of prismatic slip for two differently oriented crystals is shown in Fig. 7, where it may be seen that the bands are well defined and show a reasonable regularity of spacing. It is interesting to note, however, that the character of the bands differs in the two cases, suggesting an orientation dependence on the appearance of these bands. More will be said concerning the nature of slip bands in another paper on this study, which will deal with manifestations of glide.

It is singularly significant that, no matter how

Fig. 7—Appearance of type I prismatic $\{10\bar{1}0\}$ slip in titanium. X100.

Fig. 8 — Original orientations of coarse crystals studied in tension.

complex the deformation, in no case was slip on the basal plane (0001) established. The absence of basal slip is a glaring contradiction to the general rule of slip behavior in hexagonal close-packed metal crystals (magnesium, zinc, and cadmium). Admittedly, the orientations of a large number of these coarse crystals were similar (as might be expected from the technique used in producing them), yet on the whole the spread appears sufficient to establish $\{10\bar{1}0\}$ prismatic slip as the predominant slip mechanism. The spread in crystal orientations for the tension studies is shown in the standard stereographic triangle of Fig. 8, and it may be seen that there is a paucity of orientations in one region of the triangle. It is not possible, therefore, to rule out definitely an orientation effect with regard to the absence of basal slip.

However, the complexity of the stress pattern in some of these crystals, as a result of the method of deformation and the contiguity of grain boundaries, would be expected to encourage slip on all potential planes. In view of these considerations, it is believed that, with the possible exception of a small range of critical orientations, there is little probability of basal slip in the plastic deformation of titanium crystals of this purity for tests at room temperature.

Unfortunately, the method of stereographic analysis described above does not permit the determination of the slip direction in the planes of slip. Nevertheless, it is noteworthy that both the prismatic $\{10\bar{1}0\}$ and the first order pyramidal $\{10\bar{1}1\}$ planes contain a $\langle 11\bar{2}0 \rangle$, which is both the direction of closest packing and the slip direction in the hexagonal close-packed lattice. In order to determine experimentally the slip direction for $\{10\bar{1}0\}$ slip, it was necessary to follow by X-ray analysis the movement of the specimen axis during extension by ascertaining the crystal orientation at various stages of extension. This follows from the geometrical considerations of glide, which predict a movement of the specimen axis of the crystal toward the operative direction of glide. Fig. 9 shows examples of the application of this method, and it may be seen that in each case a type I digonal axis of indices $\langle 11\bar{2}0 \rangle$ is the effective slip direction. Therefore, the close-packed direction in these crystals is preserved as the slip direction despite the change in the slip plane. This is not too surprising, since it has been established that the slip direction is a more fundamental property of a metal than the slip plane. For example, in aluminum¹¹ and magnesium² at ele-

vated temperatures, and in several body-centered cubic metals¹²⁻¹⁴ slip can occur on more than one plane, but the direction of slip is always the same. In view of this, the assumption will be made that the direction of slip for first-order pyramidal glide is also a $\langle 11\bar{2}0 \rangle$ direction. This could not be determined experimentally in view of the secondary nature of this type of slip.

Twinning on the pyramidal planes type II, order 1 $\{11\bar{2}1\}$ and order 2 $\{11\bar{2}2\}$, as well as on the pyramidal planes type I, order 2 $\{10\bar{1}2\}$, is also a contradiction to the general plastic behavior of hexagonal close-packed metals, where twinning has been found to occur solely on the $\{10\bar{1}2\}$ planes at room temperature. Moreover, the extensive twinning indicates that this mechanism of flow plays an important role in the deformation of titanium. In general, it was found that twinning occurred most frequently on planes of the types $\{10\bar{1}2\}$ and $\{11\bar{2}1\}$; whereas $\{11\bar{2}2\}$ twinning was observed only at specimen edges (see Fig. 10), or in grains which exhibited marked multiplicity of slip and twinning as a result of surrounding stress conditions.

Fig. 9—Determination of the slip direction from the lattice rotation in the course of extension of titanium crystals.

A particularly notable feature regarding the observed twin markings is the considerable variation in their appearance, as typically illustrated in Fig. 11. It may be seen that twins of the $\{10\bar{1}2\}$ type are thick and lens-shaped, similar in habit to those of the same crystallographic form observed in cadmium, zinc, magnesium, and beryllium. In sharp contrast to this, the $\{11\bar{2}1\}$ twins appear as narrow lamellae, much like the Neumann bands characteristic of twinning in iron. The thickness does not appear to vary along the length of these twins and is rarely found to exceed five microns. Moreover, as may be seen from Fig. 6, these twin markings frequently traverse the entire width of the crystal, display an unusual regularity in their spacing, and often exhibit a stepped discontinuity which corresponds to twinning on another plane of the form $\{11\bar{2}1\}$. In these respects, the appearance of these twins is reminiscent of the formation of slip bands, and the stepped character is analogous to the cross-slip observed in α brass¹⁵ and aluminum¹⁶ crystals.

The infrequent occurrence of the $\{11\bar{2}2\}$ type twins does not permit an accurate description of their shape. However, the limited observations do indicate that the nature of these twins represents an

Fig. 10—Appearance of $\{11\bar{2}2\}$ twins at specimen edge. X100. Area reduced approximately 60 pct for reproduction.

intermediate position between the extreme shapes characteristic of the twinning on the $\{10\bar{1}2\}$ and $\{11\bar{2}1\}$ planes. It is interesting to note that the $\{11\bar{2}2\}$ twins of Fig. 10, which were formed at the edge of the specimen, show a distinct preference for appearing in pairs.

A consideration of the variation in the thickness of twin lamellae and their corresponding shear values in different metals suggests that a correlation between the magnitude of shear and the characteristic shape of twins is possible: For example, the thick lenticular deformation twins in zinc are associated with a shear of 0.143 in contrast with a shear of 0.707 for the thin Neumann bands in iron. This variation in twin thickness with magnitude of shear was very recently pointed out by Cahn,¹⁷ who further substantiated this association with his excellent results on the complex twinning behavior in the deformation of uranium. It was argued that the greater the twinning shear, the greater will be the elastic stresses resisting further growth of a twin, so that a new lamella will be started in its immediate vicinity in preference to the continued growth of the old twin. Thus, the greater the value of the twinning shear, the finer will be the twin lamellae. Although this rule is only an approximation, it does explain some experimental observations on the occurrence of twins in some metals, as well as the gross variation in twin shapes from metal to metal.

Unfortunately, in the present investigation the values of shear associated with the three types of twinning cannot be directly calculated, since it was not possible to determine experimentally the necessary twinning elements. However, with regard to the $\{10\bar{1}2\}$ twins, the equivalent $\{10\bar{1}2\}$ plane may be adopted as the "2nd undistorted K_2 plane"¹ in line with the behavior of zinc.⁷ On this basis, the plane of twinning shear is a $\{11\bar{2}0\}$ plane, and the amount of shear is 0.173. For the twins of the form $\{11\bar{2}1\}$ and $\{11\bar{2}2\}$, it is unlikely that their respective equivalent planes are K_2 planes, since the corresponding values for the magnitude of shear would be unreasonably large. However, a consideration of the crystallographic geometry of twinning¹ does permit a speculative evaluation of the shear, which for $\{11\bar{2}1\}$ twins is 0.63 and for the $\{11\bar{2}2\}$ twins is either 0.245 or 0.53. Although these calculated shear values are questionable in view of the many assumptions involved, they do serve to indicate that the thinner twins are associated with greater values of shear, in agreement with the work of Cahn.¹⁷

To summarize the experimental observations of the slip and twinning elements, it may be said that at least nine slip systems and eighteen twinning planes can contribute to the plastic flow of coarse

titanium crystals at room temperature. This is in contrast to three slip systems (basal glide) and six twinning planes (second-order pyramidal planes, type I) in the metals magnesium, zinc, and cadmium. For the purpose of clarification, the slip and twinning planes observed in the deformation of titanium are illustrated in the hexagonal lattice of Fig. 12.

Discussion of Results

Mechanism of Slip: The presence of first-order pyramidal slip $\{10\bar{1}1\}$ as a secondary slip system in titanium is similar to the behavior of magnesium^{2,18} which has a c/a ratio slightly less than the ideal. Slip on these planes in titanium occurs rarely, and the unresolvable nature of their appearance makes their detection difficult. This does not appear to be the case in magnesium at elevated temperatures.¹⁸

The predominance of type I prismatic slip $\{10\bar{1}0\}$, on the other hand, and the apparent absence of basal slip (0001) is significant; since this behavior suggests (in accordance with the general rule for slip) that in the titanium lattice the atomic density and interplanar spacing of the prismatic planes are greater than for the basal plane. This might very well be the case in titanium, if the implications of Fig. 13 are considered. The upper diagram in the figure represents the space pattern of atoms in the close-packed hexagonal structure of titanium, while the lower diagram represents the arrangement of atoms as viewed in the direction indicated by the arrow, i.e., along a $\langle 11\bar{2}0 \rangle$ direction. Therefore, in the lower diagram the arrangement is along alternate prismatic planes of the form $\{10\bar{1}0\}$. For reasons of clarity, the three atomic sites within the body of the cell have been drawn as open circles, while those forming the simple hexagonal lattices have been drawn as solid circles.

If the atoms of the two adjacent prismatic planes are considered as belonging to a single corrugated plane or band, as suggested by the dashed lines in the lower diagram of Fig. 13, it can be shown that both the atomic density and interplanar spacing are greater for the prismatic planes than for the basal planes. This is readily seen from a consideration of

Fig. 12—Hexagonal lattice showing the position of the operative slip and twinning planes and slip direction in the plastic deformation of titanium at room temperature.

Slip planes: ABHG—prism planes, type I; of the form $\{10\bar{1}0\}$. GHM—pyramidal planes, type I, order 1; of the form $\{10\bar{1}1\}$. Twinning planes: GHN—pyramidal planes, type I, order 2; of the form $\{10\bar{1}2\}$. GIM—pyramidal planes, type II, order 1; of the form $\{11\bar{2}1\}$. GIN—pyramidal planes, type II, order 2; of the form $\{11\bar{2}2\}$.

Slip direction: OG—digonal axis, type I; of the form $\langle 11\bar{2}0 \rangle$.

the lattice dimensions and the unit cells depicted to the right of the diagrams in Fig. 13. Values for these properties, which were calculated by taking $a = 1$ and $c = 1.587$, are listed in Table II, which also includes for comparison those for magnesium, zinc, and cadmium. It is evident from the tabulated values that for zinc and cadmium the basal plane still remains the plane of maximum atomic density and interplanar spacing, whereas for magnesium the situation is reversed in favor of the prismatic planes, as in the case of titanium. Therefore, it would appear from the philosophy of this analysis that magnesium should also exhibit prismatic flow. The fact that it does not at once suggests that either the atomic density and interplanar spacing for the corrugated prismatic planes must be significantly larger than for the basal plane for the occurrence of $\{10\bar{1}0\}$ slip, or the nature of the atomic bonding is an important criterion. It might be added that this postulation of a corrugated slip plane in a close-packed crystallographic direction is quite acceptable from the point of view of the present dislocation models of plastic flow.

Mechanism of Twinning: It is apparent from the experimental observations that the twinning habit in titanium, like the slip process, is very different from that generally associated with the hexagonal metals, where for room temperature tests twinning has been found to occur solely on the $\{10\bar{1}2\}$ pyra-

midal planes. In titanium, the situation is much more complex in that twinning takes place not only on the $\{10\bar{1}2\}$ planes, but also on the $\{11\bar{2}1\}$ and $\{11\bar{2}2\}$ type II pyramidal planes. Thus, it would appear that twinning in metals of this structural class always occurs on pyramidal planes of low indices, with a definite constancy in the appearance of the $\{10\bar{1}2\}$ twins. Moreover, on the basis of this difference in twinning behavior it can be empirically stated that metals of the same crystal structure but different axial ratios may not have the same twinning elements nor exhibit the same multiplicity of twinning.

Unfortunately, the present knowledge regarding the dynamics of mechanical twinning is such that it would be difficult to speculate on the reason for the presence of three distinct twin types in titanium, as well as the peculiar choice of the twinning elements. The evidence and arguments advanced by a number of investigators¹⁰⁻²¹ on the general twinning phenomenon are conflicting, and only serve to emphasize the absence of any single criterion which can account for the observed twinning elements. From the apparent complexity of this problem, it is certain that a definite need exists for more systematic investigations and reliable data.

Effect of Slip and Twinning on Ductility: The fact that in titanium there are at least nine possible slip systems (three prismatic type I and six pyramidal type I, order 1) and eighteen twinning planes (six pyramidal type I, order 2, six pyramidal type II, order 1 and six pyramidal type II, order 2) might very well account for the ability of the metal in its pure form to undergo severe amounts of plastic deformation. For example, it is well known that titanium can be cold-rolled above 90 pct reduction in thickness without serious cracking. This is particularly noteworthy in view of the fact that magnesium, which also has a c/a ratio less than the ideal (1.633), can be cold-rolled no more than 50 pct even in its high purity form. In contrast with titanium, this lack of ductility in magnesium at

Fig. 13—Crystal structure of α titanium illustrating arrangement of atoms in corrugated configuration.

Table II. Comparison of Atomic Density and Interplanar Spacing for Type I Prismatic and Basal Planes

Metal	c/a Ratio	$\{10\bar{1}0\}$ Plane		(0001) Plane	
		Atomic Density $2/ac$	Interplanar Spacing, $a\sqrt{3}/2$	Atomic Density $2/a^2\sqrt{3}$	Interplanar Spacing $c/2$
Ti	1.587	1.260	0.866	1.155	0.794
Mg	1.624	1.231	0.866	1.155	0.812
Zn	1.856	1.078	0.866	1.155	0.928
Cd	1.886	1.060	0.866	1.155	0.943

Fig. 14—Sign in the change in length along the c -axis due to twinning on a $\{10\bar{1}2\}$ plane. Solid line, crystal; dashed line, twin.

room temperature can be attributed, in part, to the presence of only three slip systems (basal glide) and six twinning planes (six pyramidal type I, order 2). Certainly, the contribution by twinning to the extent of plastic deformation in titanium is much more important than in the other hexagonal metals (magnesium, cadmium, and zinc).

An equally important consideration which can influence the degree of plasticity, particularly in hexagonal crystals, is the sign in the change in length along the c -axis due to twinning. Considering twinning on the planes of the form $\{10\bar{1}2\}$, it can be shown that depending upon whether the c/a ratio is less or greater than the value 1.732 there results an extension (<1.732) or a compression (>1.732) in the direction of the c -axis, as shown schematically in Fig. 14. Thus, in both magnesium and titanium twinning on the $\{10\bar{1}2\}$ planes cannot occur on cold rolling, since the twinning action can only result in a compression in the flow direction (i.e., rolling direction) as long as the basal plane is either parallel to or slightly inclined to the rolling plane, as is the case in these metals. Unlike magnesium, however, in titanium twinning occurs on the $\{11\bar{2}1\}$ and $\{11\bar{2}2\}$ planes in addition to the $\{10\bar{1}2\}$ planes, and it is expected, therefore, that this would favor greater deformation by rolling than can be hoped for in magnesium which twins only on the $\{10\bar{1}2\}$ planes at room temperature.

Texture Relationships: Another property of titanium which suggests a different mechanism of plastic flow than that found in the more common hexagonal close-packed metals is the preferred orientation developed in severely cold-rolled sheets. According to both Clark³ and McHargue,⁴ the texture in these sheets can best be described as one in which the $[10\bar{1}0]$ direction is parallel to the rolling direction and the (0001) plane is inclined approximately 25° to the rolling plane in the transverse direction. In contrast to this, the metals cadmium, zinc, and magnesium^{22-28, 25-28} have a texture in which there is a definite spread of the basal plane normals in the rolling direction. Moreover, in these metals there is a tendency for the $[11\bar{2}0]$ direction rather than the $[10\bar{1}0]$ direction to be parallel to the rolling direction. Therefore, the essential difference between these textures is in the direction of basal tilting, and in the direction parallel to the rolling direction. On the other hand, in zirconium (with a c/a ratio similar to titanium) McGeary and Lustman⁶ have found that the basal plane is tilted in the same manner as in titanium, and the $[10\bar{1}0]$ direction is also parallel to the rolling direction.

Although it is unwise to predict the mechanisms

of plastic flow from deformation textures, nevertheless this evidence does strongly support the general conclusion deduced from this investigation that the slip and twinning elements in titanium are different from those of magnesium, zinc, and cadmium, which have greater c/a ratios. For example, the coincidence of the $[10\bar{1}0]$ direction with the rolling direction for titanium can very well be explained by the duplex slip rotation resulting from the simultaneous operation of two $\langle 11\bar{2}0 \rangle$ directions on two $\{10\bar{1}0\}$ prismatic planes, whereas for the metals zinc, cadmium, and magnesium the crystallographic significance of the rolling direction results from slip on the basal plane in a single $\langle 11\bar{2}0 \rangle$ direction.

Another interesting consequence develops from the cold-rolled texture of titanium and the observation²⁴ that the strength of severely cold-rolled titanium sheets is greater in the transverse than in the rolling direction. From a consideration of the (0001) pole figure, it is natural to expect that if basal slip occurred in the plastic deformation of titanium, the yield strength of the sheets (because of the direction of tilting of the basal plane) would be much less in the transverse direction. Since this is not the case, it must be inferred that slip occurs more easily on another set of planes, which is what has been established in this investigation.

Conclusion

The slip and twinning elements have been determined in deformed coarse crystals of arc-melted 99.77 pct Ti (diameter of crystals, 2 to 8 mm). The method of identification was based on the use of a stereographic plot of a back-reflection Laue photograph describing the region where slip and twinning were observed. A number of these stereographic analyses showed that at least two types of slip and three twin types are operative in the plastic deformation of these crystals. The slip planes are of the type $\{10\bar{1}0\}$ and $\{10\bar{1}1\}$, while the twinning planes are of the type $\{10\bar{1}2\}$, $\{11\bar{2}1\}$, and $\{11\bar{2}2\}$. In no case was slip on the basal plane (0001) established.

In the case of the predominant $\{10\bar{1}0\}$ slip, the direction of slip was determined by following the movement of the specimen axis during extension by ascertaining the crystal orientation at various stages of extension. In all cases a type I digonal axis of indices $\langle 11\bar{2}0 \rangle$ was the effective slip direction.

Microscopic observations on the appearance of twins disclosed a distinct difference in their shapes. The $\{10\bar{1}2\}$ twins are thick and lenticular, whereas the $\{11\bar{2}1\}$ twins appear as thin lamellae similar to the Neumann bands in iron. A consideration of the geometry of twinning suggests that the characteristic shapes are related to the amount of twinning shear, in agreement with the hypothesis recently proposed by Cahn.¹⁷

The slip mechanism was discussed on the basis of the difference in c/a ratios for the common hexagonal close-packed metals. This led to a postulation of type I prismatic slip on corrugated planes. Some considerations were also advanced regarding the apparent marked ductility of this metal in contrast to the other hexagonal metals.

Acknowledgments

The authors wish to extend their gratitude to F. C. Perkins who carried out much of the experimental program, and to M. Miller who prepared

specimens for metallographic studies. Thanks are also due to V. Hannaford and A. VanRiper for the X-ray orientation determinations. The work reported herein was supported by the Office of Air Research, Contract No. AF-33-038-16031.

Observation on Scaling of Iron

by W. J. Wrazej

THE measurements on the formation of multi-layered scales on pure iron¹ and the metallographic examination of the produced layer of FeO, Fe₃O₄, and Fe₂O₃ shown in micrographs² throw much interesting light on this apparently well-known subject. Professor Paidassi announced³ that in a few months' time further results are going to be published with regard to the growth of Fe₃O₄ and Fe₂O₃ layers on an Armco iron as a function of temperature. Because of the very thin layers of Fe₂O₃ which are

shown by Paidassi (Fig. 10 of ref. 2) when samples were scaled in air at 700°C for 4 hr and because this is not in agreement with the present author's previous observations, the following experiment was recently carried out.

Polished cylindrical samples 13/64 in. in diam and 1/4 in. long from electrolytic iron used for spectrographic work (Hilger, H.S. Iron rods, F.693) and an Armco iron sample 1/4 in. in diam of the same length were suspended in a muffle furnace on Nichrome wire and annealed in air for 4 hr at 700°C \pm 5°C. Because of the known easy peeling off of the Fe₂O₃ layer which is mainly in the form of powder (purple red dust on the surface) the samples were protected against any draft and shock. After annealing, the samples were cooled in air and placed in the mount-

ing device and mounted in transparent lucite at $150^\circ C$ under a pressure of 5000 psi. The pressure was considered to be essential to retain the deposits of scales on the surface of the sample during the abrading on emery papers, i.e., to make them stick closer to the surface.

After careful abrasion with "no pressure" on emery papers and polishing on nylon with alumina, the samples were examined in unetched and etched (4 pct picral) conditions. The ratio of Fe_2O_3 to Fe_3O_4 (Figs. 1 and 2) appears to be greater than that shown by Paidassi in Fig. 10a.

The examination of the edges of the samples along the circumference revealed distinct and characteristic variations in the thickness of the layers as shown in Figs. 3 and 4, the samples in these instances were additionally etched for 60 sec. This additional etching did not change the appearance of the layer of scales. The ratio of all the three layers along the examined edges in all samples varies considerably.

There were some other important features to be noted. In some places the layers of Fe_2O_3 are extremely thin or entirely missing in spite of careful handling of the samples because of spontaneous peeling off of the scales. In some positions on the samples blisters of Fe_2O_3 are visible which evince that the low coherence of these scale particles is responsible

for the peeling off of this layer. Some pieces of Fe_2O_3 scale are shown trapped by lucite, see Figs. 3 and 4.

It is generally accepted² that a layer of iron scales consists of 85 to 95 pct of FeO covered by Fe_3O_4 layer constituting 10 to 15 pct and a layer of Fe_2O_3 amounting to about 0.5 to 2 pct of the total thickness of the scales. It is of interest to note that this assumption is not in accordance with the observed features. The result of many measurements has indicated that the ratio of the thickness of particular layers in the scale crust is as follows:

$$(Fe_2O_3 + Fe_3O_4):FeO \text{ as } 20:80$$

where $Fe_2O_3:Fe_3O_4$ is at least 1:1 and might be locally as much as 2:1 as evinced in these particular samples.

In showing such features illustrated in Figs. 1 to 4 the purpose is to draw attention to the fact that the technique used in handling the microsamples can greatly influence the apparent thickness of the Fe_2O_3 layer.

Mechanical Properties of High Purity Ti-Al Alloys

by H. R. Ogden, D. J. Maykuth, W. L. Finlay, and R. I. Jaffee

Titanium with up to 7.5 pct Al forms single-phase α alloys that are work hardening, not heat treatable, and ductile as welded. The high aluminum γ phase alloys are not usefully ductile, despite their low hardness, but they have excellent oxidation resistance and hot hardness.

LITTLE has been published on the effect of aluminum on the mechanical properties of titanium, despite the fact that two of the first four commercial alloys released by titanium alloy producers contained aluminum as an important alloying ingredient. These were both α - β type alloys, one containing 4 pct Al and 4 pct Mn and the other containing 3 pct Al and 5 pct Cr. However, neither of these alloys reflects the true alloying nature of aluminum, since each contains important amounts of the β -stabilizing addition, manganese or chromium.

In a previous publication on the constitution of Ti-Al alloys,¹ the authors showed that aluminum had a high solubility in α titanium and was strongly α stabilizing in nature. About 25 wt pct Al is soluble in α titanium at room temperature. With as little as 5 pct added aluminum, the α transus temperature is increased from 882° to 970°C, and the correspond-

ing β transus to 995°C. The first intermediate phase in the Ti-Al system is the ordered face-centered tetragonal TiAl phase, which extends from 34 to 46 wt pct Al.

The present paper presents hardness data over the entire titanium-rich region of the system, through the TiAl phase, and mechanical property data on the alloy range capable of being fabricated.

Methods of Investigation

The materials used and general preparation of alloys, as well as experimental techniques used in the investigation of Ti-Al alloys, have been adequately described.² Briefly, the preparation consisted of arc-melting the desired amount of high purity aluminum (99.99 pct purity) and iodide titanium (maximum hardness 100 Vickers, as deposited) together on a water-cooled copper hearth under a partial pressure of argon. The resulting button ingot was of such form that it could be fabricated without further treatment.

All work was done using ingots weighing 10 to 15 g, which were hot-rolled to strip form whenever possible. Tensile samples were 3.25 in. long, 0.5 in. wide, and 0.040 in. thick, with a reduced section 1.25 in. long by 0.250 in. wide. The gage length used was 1 in. Electrical strain gages mounted on the

Fig. 1 — Mechanical properties of annealed Ti-Al alloys.

tensile samples were used to obtain stress-strain curves, and data for flow curves were obtained by using dividers to measure the larger strains at each 0.01 in. elongation.

Modulus of elasticity values at elevated temperatures were obtained using the dynamic method described by Andrews.⁸ Samples used in this work were 3 in. long, 0.250 in. wide, and 0.040 in. thick. Subsequent to obtaining dynamic modulus values, the samples were machined into tensile specimens, and the modulus of elasticity was checked in tension using both Tuckerman extensometers and electrical strain gages.

Elevated temperature hardness measurements were obtained using an Amsler-Vickers hardness tester with a small resistance furnace mounted on the anvil and a diamond penetrator mounted in a heat-resistant steel chuck. A protective atmosphere of dried high purity argon was used to prevent oxidation of the specimens. Hardness impressions were taken at the desired temperatures, and measurements were subsequently made at room temperature.

Fabrication and Annealing Characteristics

All ingots were fabricated by hot rolling at 850°C. Since aluminum increases the temperature range of α - β transformation, this corresponded to fabrication in the α field. The alloys with up to about 7.5 pct Al could be rolled to satisfactory strip, although at the higher aluminum contents progressively more severe edge cracking of the strip was noticed. The alloys with more than 7.5 pct Al cracked badly

when rolled at 850°C. At higher rolling temperatures, alloys containing from 8 to 16 pct Al rolled somewhat better than at 850°C, but even at rolling temperatures up to 1250°C, the fabricated sheet was unsuitable for testing. Based on fabrication characteristics alone, the usable range of Ti-Al alloys has been established as between 0 and 7.5 pct Al.

Hot-rolling scale was removed mechanically by grinding on emery cloth. A thin layer of the base metal was also removed by grinding to eliminate any contamination caused by diffusion of nitrogen or oxygen during rolling. It was established by hardness-penetration measurements that the diffusion layer was less than 0.001 in. thick after the rolling operation.

The annealing treatment chosen for these alloys was 3½ hr at 850°C in vacuum, followed by furnace cooling. This treatment produced a completely recrystallized α structure with a grain size between 0.04 and 0.10 mm. All tensile properties were obtained on alloys annealed in this condition.

Aluminum restricts the amount of cold work that can be given to titanium. Thus, although pure

Fig. 3—Effect of aluminum content on the Vickers hardness of titanium.

titanium can be cold-rolled without cracking to reductions greater than 95 pct and Ti-Al alloys with up to 3 pct Al to reductions greater than 80 pct, alloys containing 4 to 5 pct Al edge crack at 70 pct reduction, and the 7.5 pct Al alloy starts edge cracking at 30 pct reduction. Aluminum increases the recrystallization and softening temperatures of titanium. By a series of 1 hr reheats on 40 pct cold-rolled metal, it was found that pure titanium softened and recrystallized at about 600°C, while a 5 pct Al alloy softened and recrystallized at 800°C. Microscopic examination of Ti-Al alloys rolled at 850°C and annealed 3½ hr at the same temperature indicated that finer α grain sizes were obtained with the alloys of higher aluminum content. For these conditions of fabrication, the following approximate α grain sizes were observed: Ti, 0.1 mm; 1 pct Al, 0.075 mm; 4 pct Al, 0.05 mm; and 7.5 pct Al, 0.04

Fig. 2—Effect of temperature on the dynamic elastic moduli of Ti-Al alloys.

Table I. Modulus of Elasticity Values for Ti-Al Alloys at Room Temperature

Composition, Pct (Balance Ti)	Modulus of Elasticity, 10 ⁶ Psi			
	Dynamic Method	Electric-Strain-Gage Method	Tuckerman-Extensometer Method	Tension Method, Average
100 Ti	15.4	15.9	15.8	15.7
2.5 Al	15.8	16.4	16.3	16.1 ^a
5 Al	16.6	16.7	17.3	16.8 ^a

Fig. 4—Cross section and surface hardness of Ti-Al alloys annealed 3½ hr at 850°C after rolling at 850°C.

mm. This effect most probably is caused by the increased recrystallization temperature promoted by aluminum, rather than by any intrinsic grain-refining action of aluminum.

Mechanical Properties

Tensile Properties: Tensile properties of the workable alloys containing between 0 and 7.5 pct Al, as annealed 3½ hr at 850°C, are shown in Fig. 1. Strength increases at a moderate rate up to 4 pct Al, at which point further aluminum additions have a considerably greater strengthening effect. The greatest increase in strength for 1 pct of aluminum added occurs between 4 and 5 pct. The ductility of the alloys remains quite high for alloys containing up through 7.5 pct Al, giving no indication of the poor hot-workability of alloys with the higher aluminum content.

Modulus of Elasticity: The modulus of elasticity values for several alloys are given in Table I. These were obtained using the dynamic and the tension methods. The results obtained using the dynamic method are slightly lower than obtained in tension, but both methods show that additions of aluminum increase the modulus of elasticity of titanium about 200,000 psi for each percentage of aluminum added.

The effect of temperature on the modulus of elasticity of Ti-Al alloys is shown in Fig. 2. These data were obtained using the dynamic method. The modulus values decrease linearly with increasing temperature at a rate of about 1×10^6 psi for each 100°C rise in temperature.

Hardness-Composition Data: The effect of aluminum on the Vickers hardness of iodide titanium is shown in Fig. 3. Hardness increases rapidly with increasing aluminum content up to a peak at about 26 pct Al, the terminal solubility of aluminum in α titanium. In the two-phase α - γ region, the hardness drops linearly until the γ phase is reached. The hardness of the γ phase is quite low and remains fairly uniform throughout the composition limits of this phase.

Anisotropy: When α Ti-Al alloys have been rolled and annealed at temperatures in the α field, the hardness of the rolled strip on the rolling plane is markedly higher than its hardness in planes perpendicular to the rolling plane. This results from the preferred orientation of the hexagonal basal planes parallel to the rolling surface. For Ti-Al alloys rolled and annealed at 850°C, the hardness differential increases from essentially nil for pure titanium to 75 Vickers points for the 7.5 pct Al alloy, as shown in Fig. 4. Anisotropy effects are more pronounced when the alloys are cold-rolled and annealed. For example, a 2 pct Al alloy cold-rolled

and annealed at 850°C had a hardness differential of 97 Vickers points, compared with 38 Vickers points when rolled and annealed at 850°C. Because of these anisotropy effects, it is mandatory to specify the direction of hardness measurements and the prior treatment given to the alloy when considering the hardness of wrought Ti-Al alloys, or, for that matter, of any wrought titanium α alloy.

There appears to be little or no anisotropy in annealed Ti-Al alloy sheet longitudinal or transverse to the direction of rolling. For cold-rolled sheet, the normal anisotropy found with one-phase alloys would be expected, however.

Hardness-Strength Correlations: Correlation between ultimate strength and cross-sectional Vickers hardness for Ti-Al alloys is the same as was found

Fig. 5—Correlation of Vickers hardness and ultimate strength of annealed Ti-Al alloys.

Fig. 6—Effect of temperature on Vickers hardness of Ti-Al alloys.

Fig. 7—Flow curves (true stress vs true strain) for Ti-Al alloys annealed 3½ hr at 850°C.

previously for alloys of titanium with oxygen, nitrogen, and carbon.² The ultimate tensile strength is approximately equal to 400 times the Vickers hardness number. The surface hardness vs strength correlation is not a straight line, but is curved concave to the hardness axis, as shown in Fig. 5.

Hot Hardness: The effect of temperature on the hardness of several Ti-Al alloys is shown in Fig. 6. As is characteristic of the elevated-temperature strength properties of titanium alloys, there is no initial plateau in hardness. Starting from room temperature, hardness decreases linearly with increasing temperature up to 600°C, above which a

Fig. 8 — Yield strength-cold work curves for Ti-Al alloys calculated from flow curves.

greater hardness decrease occurs with increasing temperature.

Flow Properties: The flow curves of Ti-Al alloys rolled and annealed at 850°C are given in Fig. 7. The flow constants, corresponding to the equation, $\sigma = A\delta^n$, are given in Table II. The strain coefficient, A , which gives an indication of the magnitude of the strengthening effect in the cold-rolled condition, remains about the same as the aluminum content is increased from 0 to 4 pct. For alloys containing more than 4 pct Al, the A values increase rapidly with increasing aluminum content, illustrating the effectiveness of aluminum in quantities over 4 pct. In general, the n values decrease as the aluminum content is increased. Strain hardening, which is directly measured by n as the percentage increase

Table II. Flow Equation Constants for Ti-Al Alloys

Composition	Strain Coefficient, A , Psi	Strain Exponent, n	Strain at Maximum Load, δ_m , In. per In.
100 Ti	84,000	0.25	0.30
1 Al	86,000	0.19	0.24
2 Al	78,000	0.12	0.16
3 Al	84,000	0.11	0.07
4 Al	87,000	0.11	0.08
5 Al	96,000	0.07	0.06
6 Al	112,000	0.09	0.07
6.5 Al	114,000	0.07	0.06
7.5 Al	129,000	0.07	0.14

in flow stress per percentage increase in strain, decreases with increasing aluminum content.

Uniform elongation in tension is recorded in Table II as the observed strain at maximum load. Where the flow equation applies, this is also equal to n for annealed materials. Uniform elongation decreases with increasing aluminum content and is reasonably close to n up to 6.5 pct Al. It appears to increase again at 7.5 pct Al, despite the fact that n remains low. This may be caused by a greater sensitivity of this alloy to the biaxial state of stress or to strain rate after necking occurs.

The effect of cold work on the yield strength can be calculated from the flow-curve data using the relationship, $\delta = \ln L/L_0 = \ln 1/(1-R)$, where R is the fraction reduction in cold working. These data are shown in Fig. 8 and illustrate further how aluminum in solid solution decreases strain hardening of titanium. A comparison of these curves with those previously obtained for alloys of carbon, oxygen, and nitrogen⁸ indicates that the work-hardening charac-

teristics of Ti-Al alloys are very similar to those of the alloys of titanium with carbon, oxygen, and nitrogen.

γ Phase Alloys: All attempts at fabricating alloys within the composition limits of the γ phase were unsuccessful even though this phase has a relatively low hardness, as shown in Fig. 3. The γ alloys were brittle at room temperature, except when deformed by slow compression. They could not be forged or rolled at any temperature up to 1250°C, the highest temperature used in fabricating attempts. These alloys have excellent retention of hardness at elevated temperature. Hot hardness tests conducted at temperatures up to 800°C showed that they maintained a hardness of 200 Vickers up to 500°C without any drop at all, and then decreased slowly to 130 Vickers at 800°C.

In order to obtain information on the mechanical properties of the γ phase, slow compression tests were used to determine the modulus of elasticity, compressive yield strength of the γ phase at room temperature, and some idea of the deformability of these alloys. The test was conducted at a strain rate of 0.015 per min, and was continued until a total reduction of 8 pct was reached. At this point, there were only a few small secondary tensile cracks in

Fig. 9—Effect of quenching from the β field on Vickers hardness of α -annealed Ti-Al alloys.

the specimen. The results are shown in Table III. The high modulus of elasticity is particularly noteworthy. The yield strength is about the magnitude that would be expected from the hardness of γ alloys.

Effects of Heat Treatment

The work on the constitution of Ti-Al alloys¹ showed that the two-phase α - β field was relatively narrow, and it extended to higher temperatures as the aluminum content increased. The β phase can not be retained on quenching, and transforms martensitically to α . However, quenching from the β field would not be expected to produce drastic hardening effects, because the solubility of aluminum in α titanium is greater than that in β . Also, because the terminal α solubility is so much higher than the aluminum contents in the workable alloy range, age-hardening effects would not be expected, either. These probabilities were borne out by experiment.

Fig. 9 shows the Vickers hardness of Ti-Al alloys

Deformation without cracking	At least 8 pct

rolled and annealed at 850°C and also of the same alloys heated for ½ hr in the β field and water quenched. The hardness of the β -quenched alloys, which are isotropic, is bracketed by the surface and cross-section hardness in the original α worked-and-annealed condition. Clearly there was no hardness increase involved in the martensitic transformation resulting from quenching from the β field. Subsequent aging for long periods of time from 300° to 600°C in the α field after β quenching does not increase hardness by either an aging or transformation mechanism.

The only effective heat treatment of α Ti-Al alloys is the removal of strain hardening by annealing. Annealing characteristics of these alloys were described earlier.

Weldability

The causes for the brittle welds observed in titanium alloys, chiefly of the α - β type, are undoubtedly complex, and are probably the combined result of many factors such as freezing segregation and β -phase transformation. However, like unalloyed titanium, the single-phase Ti-Al α alloys have no heat treating effects and freeze over a narrow range, and would appear to have good potentialities for being ductile in the welded condition. Some exploratory arc welds made on these alloys showed this to be the case.

A series of annealed binary Ti-Al alloys in 0.040 in. sheet form, were arc-welded with the direction

Fig. 10—Effect of aluminum content on the density of high purity titanium.

of the weld in the rolling direction of the sheet. Welding was done in a helium atmosphere chamber using a dc tungsten-electrode arc. The conditions of welding the alloys were identical with those for welding unalloyed titanium and need not be gone into in detail here. Bend tests were conducted on the welds with the weld line perpendicular to the bending axis. This may be termed a longitudinal bend test on the weld, because the bending stresses set up in the weld are in line with the weld itself. Results of these tests are summarized in Table IV. It is apparent that the bend ductility of the weld metal and heat-affected zone is at least as good as the bend ductility of the original equiaxed α base metal.

Density

One of the prime advantages of using aluminum as an alloying addition to titanium is that it decreases the density of an already light metal. Unfortunately, only a relatively small amount of aluminum can be added while maintaining a ductile alloy. Of particular interest is the effect of aluminum on the density of alloys in the usable alloy range (0 to 7.5 pct Al). Fig. 10 shows the measured densities for these alloys and, also, the densities calculated from the lattice parameters of the α phase. The density is decreased significantly with increasing aluminum content at the rate of about 0.02 g per cu cm for each 1 pct Al added. The meas-

Fig. 11—Weight gain and hardness penetration for Ti-Al alloys heated for 24 hr at 850°C in air.

ured densities and the densities calculated from lattice parameters are fairly close, the measured densities being slightly higher than the calculated densities.

The density of a γ phase alloy (Ti-37 pct Al) was found by weight displacement in water to be 3.80 g per cu cm. This corresponds very well with the density calculated from the lattice parameter of the stoichiometric composition TiAl. The calculated value was 3.80₂ g per cu cm.

Air Oxidation

In the workable α alloy range, up to 8 pct Al, there is a moderate improvement in the oxidation resistance of titanium confirmed by aluminum. Strip specimens were exposed to still air for 24 hr at 850°C. Fig. 11 shows the results that were obtained.* The oxidation rate of titanium is lowered

* The hardness-penetration curve for unalloyed titanium corresponds to 36 hr at 850°C.

by about 40 pct by 8 pct Al. The improvement in oxidation rate by aluminum is not marked until over 4 pct Al is present. Contamination, as measured by hardness penetration into the metal, is not significantly affected by aluminum. The curves in the lower part of Fig. 11 show that the increase in hardness over the original decreases to negligible values at about the same depth, and, also, that the surface hardnesses are high. There may be some significance to the indication that the surface hardness for the 2 pct Al alloy is higher and those for the 5 and 8 pct Al alloys are lower than the surface hardness of unalloyed titanium after oxidation.

The γ phase alloys have markedly superior oxida-

Table IV. Minimum Bend Radii of Arc-Welded Ti-Al Alloys

Composition, Pct Balance Ti	Minimum Bend Radii, T*	
	Weld Zone	Base Metal
0	0	0
1 Al	0	0
2 Al	1.3	1.3
2.5Al	0	1.6
3 Al	0	1.5
5 Al	1.6	1.2
6.5Al	0.9	1.3

* Minimum bend radius is given in terms of thickness of the sheet tested (T value = MBR/thickness of sheet) for a bend through an occluded angle of 75°.

Fig. 12 — Oxidation data for a γ phase alloy.

tion resistance to unalloyed titanium. Still air oxidation tests were conducted on block samples of unalloyed titanium and 37 pct Al alloy, roughly $\frac{3}{8} \times \frac{3}{8} \times \frac{1}{2}$ in. in dimensions, for 36 hr at 850°C and 24 hr at 1050°C. Oxidation rates and hardness-penetration curves under these conditions are shown in Fig. 12. These data show that besides undergoing much less oxidation, the γ alloys are not hardened by oxygen diffusion into the metal.

Discussion

It is surprising to find so small a portion of the α Ti-Al field amenable to fabrication. In this respect, the α Ti-Al alloys bear some resemblances to the α Ti-O and Ti-N alloys. The limited workable portions of the α field found in these alloy systems are readily understandable, however, because oxygen and nitrogen dissolve interstitially in titanium. Aluminum, which is a substitutional solute in titanium, does not suffer this delimitation. X-ray diffraction measurements clearly show changing lattice constants over the entire field, with no evidence of ordering taking place. An associated fact, which may have some as yet unrecognized bearing on the situation, is that all three solutes increase the c/a ratio of the hexagonal close-packed lattice.^{1, 4} Furthermore, when this ratio approaches 1.604, the Ti-Al alloys are no longer sufficiently ductile to be fabricated by hot working. This limiting ratio occurs at about 8 pct Al. In this research, the upper limit of aluminum content that was fabricable was found to be 7.5 pct. In other work, not published, the upper limit of fabricability for binary alloys was 0.7 pct N and 1 pct O. Although data are not available on the c/a ratio of Ti-O and Ti-N alloys at these contents, it is possible that there is a limiting c/a ratio of about the same magnitude reached at about the fabricable limit of these alloys.

The γ phase alloys have some extremely desirable properties, which suggest possible applications as a high temperature material. These are its high modulus of elasticity, its low density, its retention of hardness to high temperature, and its good oxidation resistance. These alloys are limited by their brittleness and inability to be deformed by means other than slow compression.

The good ductility demonstrated for arc-welded Ti-Al α alloys suggests a solution to the problem of the poor weldability reported for titanium alloys. The suggested solution is nonheat-treatable α alloys with a narrow freezing range. The results obtained in this work indicate that the ductility of such alloys in the welded condition is equivalent to that of the annealed wrought material.

Summary

The mechanical properties of high purity binary Ti-Al alloys have been determined using small melts made under contamination-free conditions. The data obtained may be summarized as follows:

1—The workable range of Ti-Al binary alloys lies between 0 and 7.5 pct Al. Alloys containing higher than 7.5 pct are not amenable to fabrication. The γ alloys, around 37 pct, are soft, but have only limited workability.

2—Small additions (up to 3 pct) of aluminum to titanium have a moderate beneficial effect of the properties of titanium. Additions of 4 pct Al or more cause a larger increase in strength. The maximum increase in strength for 1 pct Al added occurs between 4 and 5 pct Al. Ductility remains high over the entire fabricable range.

3—Aluminum was found to decrease the density and increase the modulus of elasticity of titanium about 200,000 psi per pct Al. The increase continues with increasing aluminum content such that the modulus of γ alloy was found to be remarkably high, around 21 million psi.

4—Elevated-temperature hardness and modulus of elasticity determinations are presented which show how the hardness and modulus decrease at elevated temperatures. The γ alloys were found to maintain hardness at elevated temperature much better than the α alloys.

5—The results of heat treatment studies have shown that the fabricable alloys (0 to 7.5 pct Al) are single-phase α alloys which are not heat treatable by β quenching or subsequent aging.

6—Flow properties obtained by true stress-strain analysis have shown that the alloys are strain hardening to a considerable extent, but at a lower rate than is unalloyed titanium.

7—The workable α alloys were found to be ductile in the welded condition.

Acknowledgment

The authors are grateful to Rem-Cru Titanium, Inc., for permission to publish the results of this research, which was done at Battelle Memorial Institute under their sponsorship. They also wish to thank B. W. Gonser of Battelle for valuable suggestions and discussions which aided the progress of the research.

System Zirconium-Copper

by C. E. Lundin, D. J. McPherson, and M. Hansen

PRIOR work on the Zr-Cu phase diagram by Allibone and Sykes,¹ Pogodin, Shumova, and Kugucheva,² and Raub and Engel³ was confined largely to copper-rich alloys. The investigations of Raub and Engel were the most recent and seemingly the most complete of these. Alloys from 0 to 68.3 pct Zr were studied principally by thermal analysis and microscopic examination. These authors reported an intermetallic compound ZrCu_3 (1116°C melting point) and two eutectics, one at 86.3 pct Cu (977°C mp) and the other at 49 pct Cu (877°C mp). The solubility of zirconium in copper was reported to be less than 0.1 pct at 940°C.

The zirconium melting stock consisted of Westinghouse "Grade 3" iodide crystal bar (nominally 99.8 pct pure). It was treated by sand blasting and pickling (HF-HNO_3 solution) to remove the surface film of corrosion product, resulting from grade designation tests. The crystal bar was cold rolled to strip, lightly pickled again, and cut into pieces approximately 1/32 in. thick and 1/4 in. square. These were cleaned in acetone, dried, and stored for charging.

The high-purity copper (spectrographic grade) was supplied by the American Smelting and Refining Co. with a nominal purity of 99.99 pct. These copper rods were rolled to strip, cut into squares the same size as the zirconium platelets, cleaned in acetone, dried, and stored.

Equipment and Procedures

The equipment used for melting and annealing the zirconium binary alloys and for the determination of solidus curves has been described in connection with previous work on the Ti-Si system⁴ and in recent papers in this series describing the studies on eight binary zirconium systems.⁵⁻⁷ Techniques employed for preparing and processing the alloys were also similar to those used in the above references.

Ingots of 20 g were melted under a protective atmosphere of helium on water-cooled copper blocks in a nonconsumable electrode (tungsten) arc furnace. The ingots were homogenized and cold-worked prior to isothermal annealing to aid in the attainment of equilibrium. The specimens were heat-treated in Vycor bulbs sealed in vacuo or under argon, depending on the temperature of the anneal. Quenching was accomplished by breaking the Vycor bulbs under cold water. Temperature control was within $\pm 3^\circ\text{C}$ of reported temperatures.

Thermal analysis was primarily relied on to determine eutectic levels, peritectic levels, and compound melting points. The induction furnace incipient melting technique was also used but did not provide the accuracy obtained by thermal analysis

in this system, which involves much lower solidus temperatures than the other zirconium systems. A special technique for the determination of characteristic temperatures was employed in the case of several intermediate phases and their eutectics which displayed very small differences in melting temperatures. Specimens were sealed in Vycor bulbs and annealed at a series of very accurately controlled temperatures. Metallographic examination was then employed to reveal incipient melting. Furnaces and techniques in general were described previously.⁴ The etchant used was 20 pct HF plus 20 pct HNO_3 in glycerine unless otherwise stated.

Results and Discussion

The chemical analyses of the majority of alloys prepared for the determination of phase relationships in this system are given in Table I and a brief summary of the equilibrium anneals employed is given in Table II. In a preliminary program, alloys containing 1, 4, and 7 pct Cu were annealed for three different times at each of the temperatures 700°, 800°, and 900°C. No change in the relative amounts of phases present was detected after 350, 150, and 75 hr at the above temperatures, respectively. The times listed in Table II were accordingly chosen as a result of these preliminary tests.

Zirconium-rich alloys containing from 0.1 to 10 pct Cu were reduced by cold pressing from 58 to 8 pct, depending upon the alloy content, homogenized for 7 hr at 900°C, and then reduced 80 to 13 pct by cold rolling, again depending upon copper content. Other alloys were studied in the cast, or cast and annealed conditions.

The contracted scope of investigation for this system included the range 0 to 50 atomic pct Cu. This approximate region is shown in Fig. 1. Due to evidence of phase relationships departing considerably from those proposed by Raub and Engel³ in the 50 to 100 atomic pct range, the investigation was extended to cover this composition area rather thoroughly also. Fig. 2 is a drawing of the entire diagram. The labeling of some phase fields was omitted in Fig. 2 for the sake of clarity. An expanded view of the zirconium-rich region, with the experimental points necessary for its construction, is given in Fig. 3. The generally accepted value of Vogel and Tonn⁸ for the allotropic transformation $\alpha \rightleftharpoons \beta$, $862^\circ \pm 5^\circ\text{C}$, was employed in the construction of these diagrams. A careful study revealed that the "Grade 3" crystal bar used in this investigation actually transforms over the approximate range 850° to 870°C, due to impurities. It must be expected that this two-phase field in unalloyed zirconium will cause some departures from binary ideality in the very dilute alloys.

Zirconium-rich Alloys: The $\alpha \rightleftharpoons \beta$ transformation temperature is decreased from 862° to about 822°C by increasing amounts of copper. Thus, a eutectoid reaction, $\beta \rightleftharpoons \alpha + \text{Zr}_2\text{Cu}$, occurs at a composition of about 1.6 pct Cu. The eutectoid level was determined to lie between the alloy series annealed at 815° and 830°C. The placement of this eutectoid temperature

Fig. 1—Partial diagram of the Zr-Cu system.

Fig. 2—The Zr-Cu system.

was based principally on the structures of hypereutectoid alloys. The hypereutectoid alloys in the $\beta + \text{Zr}_2\text{Cu}$ region displayed partial eutectoid decomposition during water quenching. This phenomenon is indicated in Fig. 4, a 3.2 pct Cu alloy quenched from 830°C, in which decomposition, probably nucleated by proeutectoid Zr_2Cu crystals, is seen to progress out from the original β grain boundaries. At 815°C, Fig. 5, the structure consists of particles of Zr_2Cu in a matrix of isothermal α . Therefore, at the annealing temperatures of 830° and 815°C, the

specimens were $\beta + \text{Zr}_2\text{Cu}$ and $\alpha + \text{Zr}_2\text{Cu}$, respectively. Partial eutectoid decomposition was also noted in other hypereutectoid alloys quenched from above 822°C.

The convergence of the β solid-solution field toward the eutectoid composition, 1.6 pct Cu, is illustrated by Figs. 6 through 8, of alloys containing 1.05, 1.8, and 3.2 pct Cu, respectively, annealed at 850°C. Structures containing $\alpha + \beta$, β , and $\beta + \text{Zr}_2\text{Cu}$ are evident.

The uppermost experimental placement (980°C) of the $\beta/\beta + \text{Zr}_2\text{Cu}$ phase boundary is illustrated in Figs. 9 and 10. The extrapolation of this boundary to the eutectic temperature, 995°C, indicates a maximum copper solubility in β zirconium of about 3.8 pct.

The maximum solubility of copper in α zirconium is demonstrated by Figs. 11 and 12, showing alloys annealed at 830°C. The former, a 0.09 pct Cu alloy, consists almost entirely of α solid solution. The latter, a 0.18 pct Cu alloy, contains $\alpha + \beta$.

Within a restricted region near the eutectoid, anomalous three-phase structures, stemming from the transformation range in unalloyed zirconium, were sometimes observed. The departure from true

binary equilibrium in this region did not seriously affect the placement of the eutectoid composition and temperature.

Intermediate Phases: Surveying the system in the direction of increasing copper content, the structure in Fig. 9 is that of an alloy with 3.2 pct Cu. The structure represents β solid solution, transformed to acicular α during the quench. Fig. 13, an alloy with 10.3 pct Cu, shows primary β dendrites plus eutectic. At 20.9 pct Cu, the structure consists of 100 pct of the eutectic β -Zr₂Cu; this is depicted in Fig. 14. The intermediate phase Zr₂Cu corresponds to a theoretical composition of 25.83 pct Cu. The alloy which most nearly approaches a single-phase structure analyzed 26.9 pct Cu. Fig. 15 represents this alloy. X-ray diffraction studies indicated the structure of this alloy to be face-centered tetragonal, with the following lattice constants: $c = 3.716\text{\AA}$, $a = 4.536\text{\AA}$, and $c/a = 0.819$. The pattern of this phase is summarized in Table III.

Between Zr₂Cu and the next intermediate phase, there exists a eutectic. Fig. 16 shows this eutectic in a 37.0 pct Cu alloy. Above 37 pct Cu, primary crystals of the new phase increase in amount until, at 41.2 pct Cu, a nearly single-phase structure is ob-

tained, Fig. 17. The most probable formula for this intermediate phase is ZrCu (41.06 pct Cu). A pronounced acicularity within the primary ZrCu crystals may indicate a transformation or reaction involving this phase in the solid state. Debye-Scherrer X-ray photographs of the 41.2 pct Cu alloy in the as-cast condition and as annealed at 900° and 700°C, revealed such complicated patterns that no attempts were made to index the structures for the present work.

The next eutectic occurs at 47.6 pct Cu, shown in Fig. 18. The participating phases are ZrCu and an intermediate phase still richer in copper. Nearly 100 pct of this phase is obtained in the cast structure of a 50.2 pct Cu alloy, Fig. 19. The formula Zr₂Cu₃ (theoretically 51.09 pct Cu) was assigned to this phase. X-ray powder patterns of the 50.2 pct Cu alloy in both as-cast and annealed conditions revealed lines too numerous to index within the scope of this program.

An alloy containing 52.4 pct Cu, Fig. 20, represents the eutectic between Zr₂Cu₃ and a new intermediate phase. Between 52.4 and 60.2 pct Cu, primary crystals of this new phase increase in relative amount. Fig. 21 shows a 60.2 pct Cu alloy, consisting of primary compound crystals plus eutectic. In an alloy of 62.5 pct Cu, Fig. 22, a new type of primary crystal (hexagonal habit) appears and is surrounded by a rim of the phase which was primary in the 60.2 pct Cu alloy. Thus, a peritectic reaction takes place between the melt at about 61 pct Cu and primary hexagonal type crystals to form a peritectic phase. Fig. 23 shows the 62.5 pct Cu alloy after annealing. The peritectic reaction has proceeded considerably, but not to completion, since

† Vacuum induction furnace incipient melting data.

resorption of the hexagonal habit crystals is not complete. The peritectic phase is tentatively assigned the formula Zr_2Cu_3 (63.52 pct Cu), although it might alternatively be $ZrCu_3$ (67.63 pct Cu).

The next single-phase alloy with an open maximum, Fig. 24, contains 71.5 pct Cu. This is the copper-rich intermediate phase which has been called $ZrCu_3$ (67.63 pct Cu) by previous investigators. This designation is tentatively adopted, although in the present work single-phase alloys persist at compositions closer to the theoretical formula $ZrCu_3$ (73.59 pct Cu). Limited attempts to index the X-ray diffraction patterns obtained from as-cast and annealed (900°C) samples of the 71.5 pct Cu alloy were unsuccessful.

An alloy containing 91.1 pct Cu, Fig. 25, depicts the eutectic between $ZrCu_3$ and the copper solid solution. No alloys were made to study the limited solid solubility of zirconium in copper. This has been rather thoroughly treated in the literature.¹⁻³

Melting Point Determinations: As discussed earlier, the determination of characteristic temperatures in the Zr-Cu system required somewhat different techniques than those employed for other zirconium binary systems, because of, 1—the generally lower solidus, eutectic and peritectic levels, and 2—the very slight differences in certain adjacent characteristic temperatures. Table IV summarizes the melting data for this system. Temperature values shown on the diagrams are thermal analysis or bulb annealing figures and were chosen on the basis of the best reproducible checks.

Discussion of the Literature: There is general agreement between the present authors and Raub and Engel³ on the nature of the system between $ZrCu_3$ and copper. Melting points of the intermediate phase $ZrCu_3$ and the eutectic $ZrCu_3$ -Cu compare favorably, but the compositions are displaced slightly to higher copper contents in the present work.

In the area on the zirconium side of $ZrCu_3$, Raub and Engel reported only a eutectic between $ZrCu_3$ and an unidentified zirconium-rich phase. The present investigation has shown the existence of three intermediate phases, $ZrCu$, Zr_2Cu_3 and Zr_2Cu_5 (?), the last being peritectically formed, and three eutectics in this same region.

It is believed that any investigation based primarily on thermal analysis of these alloys might well fail to find the several structural features because of the previously mentioned close similarity

of characteristic temperatures in this alloy range. An intensive microscopic investigation of cast and heat-treated alloy structures is necessary.

Summary

The Zr-Cu phase diagram has the following features:

1—The maximum solubility of copper in β zirconium is 3.8 pct at the eutectic temperature. The solubility of copper in α zirconium is less than 0.18 pct at all temperatures. A eutectoid reaction occurs at 1.6 pct copper and $822^\circ \pm 10^\circ\text{C}$.

2—A eutectic exists at 21 pct Cu and $995^\circ \pm 10^\circ\text{C}$ between zirconium and Zr_2Cu (25.83 pct Cu).

3—An intermediate phase is formed at about 27 pct Cu and $1000^\circ \pm 10^\circ\text{C}$ which probably corresponds to the formula Zr_2Cu (25.83 pct Cu).

4—A eutectic occurs at 37 pct Cu and $928^\circ \pm 10^\circ\text{C}$ between Zr_2Cu and $ZrCu$ (41.06 pct Cu).

5—An intermetallic compound forms at 41 pct Cu and $935^\circ \pm 10^\circ\text{C}$, corresponding to the formula $ZrCu$ (41.06 pct Cu).

6—A eutectic between $ZrCu$ and Zr_2Cu_3 (51.09 pct Cu) exists at 47 pct Cu and $890^\circ \pm 10^\circ\text{C}$.

7—An intermetallic compound forms at 50 pct Cu and $895^\circ \pm 10^\circ\text{C}$, corresponding to the formula Zr_2Cu_3 (51.09 pct Cu).

8—A eutectic between Zr_2Cu_3 and Zr_2Cu_5 (tentative; 63.52 pct Cu) occurs at 53 pct Cu and $885^\circ \pm 10^\circ\text{C}$.

9—The intermediate phase designated Zr_2Cu_5 is formed peritectically by a reaction between the melt containing 61 pct Cu and $ZrCu_3$ (tentative; 67.63 pct Cu), at $1070^\circ \pm 10^\circ\text{C}$.

10—An intermediate phase exists at about 71.5 pct Cu and melts with an open maximum at $1100^\circ \pm 10^\circ\text{C}$. The formula $ZrCu_3$ (67.63 pct Cu) has been tentatively accepted for this phase on a basis of previous literature.

11—A eutectic between $ZrCu_3$ and copper exists at 91 pct Cu and $965^\circ \pm 10^\circ\text{C}$.

12—The solubility of zirconium in copper is very limited. Previous investigators, although in disagreement on exact values, agree that the solubility is less than 1 pct Zr.

Acknowledgments

The authors are grateful to the Atomic Energy Commission, sponsor of the work under Contract No. AT (11-1)-149 "Phase Diagrams of Zirconium-Base Alloys," for permission to publish this paper. Thanks are due to R. F. Domagala who supervised the heat treatment program, to C. A. Johnson for the metallographic work, and to W. Rostoker for interpretation of the X-ray diffraction patterns.

System Zirconium-Chromium

by R. F. Domagala, D. J. McPherson, and M. Hansen

On the basis of metallographic analysis, incipient melting data, thermal analysis work, and X-ray diffraction, phase relationships in the 0 to 50 atomic pct Cr region were carefully resolved. Phase relationships in the 50 to 100 atomic pct region were outlined. A single intermediate phase, ZrCr_2 , was established in the system. A eutectic and a eutectoid were found in the zirconium-rich region of the system, while a eutectic was located in the chromium-rich region. Limited solubility of chromium in both α and β zirconium was observed.

THIS is another in a series of papers on zirconium-base binary phase diagrams based on a program sponsored by the Atomic Energy Commission. The Zr-Sn,¹ Zr-Si,² and Zr-Mo and Zr-W³ systems have already been published. Previous work on the Zr-Cr system includes a partial diagram by Hayes, Roberson, and Davies⁴ and a complete diagram by McQuillan.⁵ The phase relationships reported by these authors were determined with magnesium-reduced zirconium, whereas those reported herein are based on iodide metal. Some X-ray work on the intermediate phase in this system was also reported by Hayes et al., as well as by Wallbaum.⁶ Comparisons with these data are made in the appropriate sections.

Thermal analysis, metallographic and incipient melting techniques were employed to accurately resolve phase relationships in the 0 to 50 atomic pct Cr region, while the remainder of the diagram is outlined on a basis of cast structures and thermal analysis.

A description and analyses of the metals used in the preparation of alloys for this study are included in Table I. A "low-hafnium" zirconium crystal bar (Westinghouse "Grade 3") was used. This material was produced by the decomposition of a volatile iodide onto a hot zirconium filament. The as-received crystal bar was coated with corrosion product from a standard autoclave test by which its grade designation is determined. A sand-blasting and subsequent HF-HNO₃ pickling treatment was employed to remove this contamination. The bars were cold-rolled to approximately 1/32-in. sheet, pickled again, sheared to 1/4-in. squares, washed with acetone, and stored for use.

Ingot chromium metal from National Research Corp. and electrolytic chromium flakes from Johnson, Matthey and Co., Ltd., were available as alloy additions. The ingot chromium was received in granular form. The large granules were sized by crushing,

R. F. DOMAGALA and D. J. MCPHERSON, Junior Members AIME, are Assistant Metallurgist and Supervisor, respectively, Physical Metallurgy Research, and M. HANSEN, Member AIME, is Chairman, Metals Research Dept., Armour Research Foundation of Illinois Institute of Technology, Chicago, Ill.

Discussion on this paper, TP 3481E, may be sent, 2 copies, to AIME by April 1, 1953. Manuscript, Aug. 26, 1952. Los Angeles Meeting, February 1953.

treated for iron removal, rinsed with acetone, and stored. The flakes were broken to approximately 1/8 in. with mortar and pestle, cleaned with acetone, and stored for charging.

Experimental Procedure

A nonconsumable electrode arc furnace identical to that described by Hansen, Kessler, and McPherson,⁷ was used in this work. A 400 amp dc welding generator was the source of power. To insure homogeneity, ingots were melted in a water-cooled spun copper crucible, a total of four times without opening the furnace. No difficulties were encountered in the preparation of these binary alloys. Analyzed chromium contents were found to agree very well with the intended content. Melts of pure zirconium were interspersed in the course of preparing the alloys and their hardness was measured to keep a constant check on the melting technique.

Vycor and quartz bulbs were used to contain the samples for isothermal annealing treatments. Vycor bulbs were employed for temperatures up to 1100°C, while quartz was used above this temperature. For treatments up to 950°C the bulbs were evacuated before sealing, but for higher temperatures a partial pressure of argon was admitted to the

* Johnson-Matthey chromium. All other alloys prepared with National Research chromium.

bulb before sealing. This pressure was controlled to produce 1 atm of pressure at the temperature of treatment. Sheet molybdenum, 0.003 in. thick, was used as a liner for bulbs scheduled for treatment above 1200°C. Specimen protection and support to the walls of the bulbs were provided by these liners. All treatments except homogenization were carried out in glazed porcelain tubes in electrically heated furnaces. Temperature control for anneals was held to $\pm 3^\circ\text{C}$ in general, but many runs were held to a smaller deviation. Homogenization treatments were carried out in a box-type Globar furnace. Specimen temperatures were measured with calibrated thermocouples at least twice a day for long time runs and at more frequent intervals for short time anneals. A control sample of pure zirconium was included in each bulb of isothermally annealed specimens. Specimens were quenched at the conclusion of an anneal by rapidly withdrawing the bulb from the furnace and breaking it under water.

A description of the high temperature vacuum-induction furnace and quenching technique used for the determination of solidus temperatures may be found in the literature.⁷ Thermal analysis techniques also described in the literature,⁷ were employed with success in this system because of the comparatively low temperature levels involved. The

* Alloys were pretreated before annealing as described in the text. Control samples of pure zirconium were included in each annealing treatment.

† Specimens in the region of the eutectic melted.

‡ Specimens held at 900°C for 17 hr, slowly cooled to temperature and held for time indicated, followed by water quench.

1350° and 1300°C isothermal anneals also proved useful in the delineation of the solidus curves in the zirconium-rich portion of the diagram.

Results

Table II includes the chemical analyses of all the alloys prepared for the determination of phase relationships in the Zr-Cr system, while a tabulation of all annealing treatments employed is included in Table III.

Zirconium-rich alloys containing from 0.25 to 15 pct Cr were cold-pressed from 30 to 4 pct depending upon alloy content. Alloys containing up to 40 pct Cr were then given a homogenization treatment at 1200°C for 75 hr. Ingots containing less than 22 pct Cr were then cold-rolled from 74 to 8 pct, depending upon alloy content, prior to the isothermal annealing treatments. All other alloys were employed in the arc-cast condition.

Fig. 1 shows the phase relationships in the 0 to 50 wt pct chromium region of the system. An expanded view of the eutectoid region of this system is given in Fig. 2, while Fig. 3 shows the entire diagram. Figs. 1 and 2 include most of the experimental points necessary for the construction of the diagram; some points were omitted for clarity.

Preliminary anneals of alloys containing 0.5, 2, and 5 pct Cr were made at 700°, 800°, and 900°C. No changes in the relative amounts of phases were observed after 150 hr at 700°C, 100 hr at 800°C, and 48 hr at 900°C. These data were then used to predict the times necessary to approach equilibrium at all temperatures employed in the isothermal annealing schedule.

An investigation, undertaken to establish the temperature of the allotropic transformation, $\alpha \rightleftharpoons \beta$, in "Grade 3" zirconium, manifested a range of transformation for this material. Details of this study may be found in an earlier paper on the Zr-Mo and Zr-W systems.⁸ The value reported by Vogel and Tonn,⁸ 862° $\pm 5^\circ\text{C}$, has been used for the construction of the diagram since the experimentally determined transformation range, 851° to 868°C, bracketed this temperature.

The eutectic at 18 pct Cr and 1280° $\pm 10^\circ\text{C}$ was located by the microscopic examination of as-cast alloys in this region, as well as specimens from the incipient melting and thermal analysis programs. Fig. 4 shows the eutectic structure found in an alloy containing 19.1 pct Cr employed in the thermal analysis program for this system.

Examination of isothermally annealed specimens showed the solubility of chromium in β to decrease from a maximum of 4.5 pct at the eutectic temperature to about 1 pct at 835°C, the temperature of the eutectoid reaction. Figs. 5 and 6 show a 4.4 and a 4.7 pct Cr alloy respectively, quenched from 1300°C. The former is a 100 pct retained β structure, while the latter alloy, also β , shows signs of incipient melting. Fig. 6, therefore, indicates the eutectic temperature is below 1300°C and the maximum solubility of chromium in β is less than 4.7 pct. Figs. 7 and 8 bracket the $\beta/\beta + \text{ZrCr}_2$ boundary at 950°C. The former figure is a 0.81 pct Cr alloy quenched from 950°C showing a typical transformed β structure. Fig. 8, a 1.5 pct Cr alloy quenched from the same temperature, contains crystals of ZrCr_2 in a transformed β matrix.

The eutectoid composition was determined to be 1 pct Cr, while the eutectoid temperature was found to be 835°C. The composition value is believed to be

Fig. 1—Partial diagram of the Zr-Cr system.

within ± 0.25 pct Cr of the equilibrium composition, while the temperature level determined by metallographic examination of many specimens is certainly within $\pm 10^\circ\text{C}$ of the equilibrium value. Evidence for the placement of the eutectoid level is shown in Figs. 9 and 10. The former, a 1.5 pct Cr alloy quenched from 840°C , is a typical transformed β plus ZrCr_2 structure, while the latter figure, the same alloy quenched from 830°C , contains α plus ZrCr_2 . Thus the eutectoid level should lie between the two temperatures, and was positioned at 835°C . Due to the transformation range in unalloyed zirconium frequently causing anomalous structures in the region of the eutectoid, the temperature presented is considered somewhat less precise than Figs. 9 and 10 would indicate.

Fig. 2—Expanded diagram of the zirconium-rich region of the Zr-Cr system.

Fig. 3—The Zr-Cr system.

The maximum solubility of chromium in α zirconium was determined to be less than 0.28 pct at all temperatures. Fig. 11 illustrates a 0.28 pct Cr alloy quenched after 360 hr at 820°C . ZrCr_2 particles are present in an α matrix.

Fig. 12, a 53.1 pct Cr alloy, as-cast, is nearly single phase, indicating the proximity to an intermediate phase. This intermediate phase has a maximum melting point and was identified as ZrCr_2 (53.23 pct Cr).

The identification of this phase as ZrCr_2 agrees with Wallbaum⁸ and Hayes et al.⁴ An X-ray diffraction pattern of the nearly single-phase 53.1 pct Cr alloy was made using copper $K\alpha$ filtered radiation. Interpretation of the pattern indicated the structure of the phase to be hexagonal close-packed, with the following lattice parameters:

	Observed	Calculated
c	—	8.262 Å
a	—	5.079 Å
c/a	1.65	1.627

These values compare favorably with an axial ratio of 1.633 reported by Wallbaum,⁸ who classes ZrCr_2 as MgZn_2 type (C14). Hayes et al.,⁴ however, report ZrCr_2 to be cubic of the MgCu_2 type, with $a = 7.21 \text{ Å}$.

The eutectic between ZrCr_2 and the chromium solid solution is illustrated in Fig. 13, a 69.5 pct Cr alloy employed in the thermal analysis work for this system. This alloy was slowly cooled from the liquid field.

On a basis of microscopic examination of unanalyzed as-cast specimens, the solid solubility of zirconium in chromium was shown to be less than 3 pct.

Thermal analysis and incipient melting methods were used to determine solidus curves and eutectic horizontals in this system. The data from this work are included in Table IV.

Discussion of the Literature

Phase diagrams of the Zr-Cr system have been published by Hayes et al.⁴ and McQuillan.⁵ The former authors extended their investigation from zirconium to ZrCr_2 , while McQuillan presented the

entire diagram. The general features of these two diagrams may be summarized as follows:

Hayes et al.: 1—Zr- $ZrCr_2$ eutectic at 18 pct Cr and 1380°C. 2—Maximum solubility of chromium in β zirconium, 6.2 pct at 1380°C. 3—Eutectoid $\beta \rightleftharpoons \alpha + ZrCr_2$ at 1.8 pct Cr and 805°C. 4—Negligible solubility of chromium in α zirconium. 5—Intermediate phase $ZrCr_3$, melting at 1525°C. Crystal structure: cubic $MgCu_2$ type, $a = 7.21\text{\AA}$.

McQuillan: 1—Single intermediate phase at 48 pct Cr, formed by the peritectic reaction $L + \beta \rightleftharpoons C$ at 1650°C. 2—Solubility of chromium in β zirconium decreasing sharply from about 48 pct at 1650°C to about 5 pct at 1350°C, then gradually to about 2 pct at 835°C. 3—Eutectoid: $\beta \rightleftharpoons \alpha + C$ at 2 pct Cr and 835°C. 4—Very limited solubility of chromium in α zirconium. 5—Eutectic between the intermediate phase and chromium solid solution at 70 pct Cr and about 1545°C. 6—Solubility of zirconium in chromium less than 2.6 pct at the eutectic temperature.

Comparing the features established in this work with the literature it may be seen that Hayes et al. and the present authors are in agreement on the general constitution of the zirconium-rich region, whereas McQuillan has determined a greatly different set of phase relationships. The present work, however, agrees with McQuillan that the intermediate phase and the chromium-rich solid solution form a eutectic. To a certain extent, differences in the results may be attributable to the use of different zirconium stock in the three programs. Hayes et al. and McQuillan used magnesium-reduced zirconium metal while the present work is based on alloys prepared with higher purity iodide crystal bar.

Summary

The Zr-Cr phase diagram was carefully determined to 50 atomic pct Cr. A limited amount of work was done to outline the rest of the system. The alloys prepared for this study were melted and

annealed under protective atmospheres to prevent contamination. The principal features of the diagram include:

1—The limit of solubility of chromium in β zirconium is 4.5 pct.

2—A eutectic occurs between β and $ZrCr_2$ at 18 pct Cr and $1280^\circ \pm 10^\circ\text{C}$.

3—A single intermediate phase exists in the system, at 53 pct Cr, corresponding to the formula $ZrCr_2$. This phase melts with an open maximum at $1700^\circ \pm 25^\circ\text{C}$.

4—A eutectoid decomposition of β into $\alpha + ZrCr_2$ occurs at $835^\circ \pm 10^\circ\text{C}$ and 1 ± 0.25 pct Cr.

5—The solubility of chromium in α zirconium is less than 0.28 pct at all temperature levels.

6—A eutectic occurs between $ZrCr_2$ and chromium-rich solid solution at 70 pct Cr and $1635^\circ \pm 15^\circ\text{C}$.

7—The maximum solubility of zirconium in chromium is less than 3 pct.

Acknowledgments

The authors wish to thank the Atomic Energy Commission, sponsors of this work under Contract No. AT(11-1)-149, "Phase Diagrams of Zirconium-Base Alloys," for permission to publish this paper. Special thanks are due to C. E. Lundin who supervised the preparation of alloys, C. A. Johnson who was responsible for the metallographic work, and W. Rostoker for interpretation of the X-ray patterns.

Addendum

Since this paper was submitted, an allotropy has been established for the phase $ZrCr_2$, which involves both the structures reported in this paper and by Hayes, Roberson, and Davies. Details of the allotropy are discussed by W. Rostoker in TN 148E, this issue, p. 304.

Kinetics of Thermal Reorientations in Cold Rolled Zirconium

by R. K. McGeary and B. Lustman

Orientation relationships and rates of annealing of 97 pct cold rolled zirconium have been studied by X-ray techniques, metallography, and by hardness measurements. The process of annealing occurring by the formation of domains, and their subsequent growth without recrystallization, is demonstrated.

NUMEROUS investigators¹⁻⁵ have revealed subgrain formation after annealing cold worked metal single crystals and have generally described the results in terms of a dislocation mechanism of polygonization.^{5, 6} In heavily cold rolled polycrystalline aluminum the first stages of heating cause an apparently spontaneous subdivision of regions of the deformed matrix into a great number of slightly disoriented domains followed or accompanied by rapid growth of certain domains to form a recrystallization texture.^{7, 8}

In the present investigation the isothermal rate of annealing of cold worked polycrystalline zirconium has been studied by X-ray techniques, metallography, and by hardness measurement. It will be shown that, rather than by the usual nucleation and growth mechanism,⁹⁻¹² the process of annealing can best be explained by the formation of domains early in the annealing treatment and the subsequent growth of these domains without recrystallization.

Experimental Procedure

All the experimental work was performed on an arc-melted ingot of high purity zirconium crystal

R. K. McGEARY and B. LUSTMAN, Members AIME, are associated with the Atomic Power Div., Westinghouse Electric Corp., Pittsburgh.

Discussion on this paper, TP 3454E, may be sent, 2 copies, to AIME by April 1, 1953. Manuscript, Aug. 21, 1952. Los Angeles Meeting, February 1953.

bar made by Westinghouse in a production scale deBoer unit. The weight percentage of impurities in the zirconium were as follows: C, 0.04; Fe, 0.05; Hf, 0.014; W, 0.01; Ti, Ni, and Al, 0.003; Si and N, 0.002; Cr and Cu, 0.001. Metallographically the zirconium showed only a single phase. The 4 in. diam ingot was forged at 760°C to a 1½x3 in. plate and was then rolled at 760°C to 0.150 in. thickness and annealed at this temperature for 20 min to produce an equiaxed grain structure of about 0.1 mm average grain diameter. The hot rolled plate was roller-leveled, surface ground to 0.135 in., cold rolled 83 pct reduction in thickness on a two-high mill, and then to a total reduction of 97 pct on a Sendzimir mill. The 0.004 in. strip material so produced received no subsequent mechanical treatment.

Specimens 5/8 in. square were sheared from the rolled strip and isothermally annealed at 10⁻⁵ mm Hg in an all glass vacuum system equipped with a Vycor furnace tube. The temperature data presented are the average temperatures during the runs and did not vary more than about ±3°C.

X-ray Diffraction Methods: When zirconium is drastically cold rolled, a high degree of preferred orientation results in which prism poles, {10 $\bar{1}$ 0}, are perpendicular to the rolling direction. After fully annealing this material an entirely new texture develops which corresponds to a 20° or 40° rotation of the deformation texture about hexagonal axes of

Fig. 1 — $\{10\bar{1}0\}$ pole figure for zirconium cold rolled 97 pct. Circle over cross indicates ideal orientation for $36 \pm 2^\circ$ rotation about R. D.

the annealing texture. In the present work the decrease in transmitted X-ray diffraction intensity from the prism poles perpendicular to the rolling direction has been used as a measure of the rate of thermally induced reorientation in specimens heated at various temperatures for various times. Likewise, for the same series of specimens, the increase of $\{10\bar{1}0\}$ intensity from a low value in the cold rolled

condition to a maximum in the fully annealed condition, for an orientation corresponding to a maximum on the pole figure of fully annealed material, has been used as a measure of the rate of formation of the annealing texture.

A General Electric Geiger counter X-ray spectrometer was used to measure the counting rate of the transmitted $\{10\bar{1}0\}$ diffracted intensity for all the heat treated specimens. This method is similar to that used by Decker and Harker,¹³ and Seymour and Harker,¹⁴ except that transmitted intensity rather than the reflected intensity is measured. In addition $\{10\bar{1}0\}$ pole figures for cold rolled and for fully annealed zirconium were determined.

The final thickness of the rolled strip was chosen as 0.004 in. because for molybdenum radiation the absorption correction due to variable irradiated volume of material^{15, 16} did not vary by more than 2 pct and could therefore be neglected for the 55° of rotation angles used. Therefore, the pole figures could be determined by the transmission method alone without the necessity for making absorption corrections. Counting rates for all of the experimental work in this report are quantitatively comparable since the counting rate was calibrated periodically with a standard sample. Not all of the area

of the pole figures was determined; the symmetry of the figures was established by counting rate measurements for 5° interval rotations of the specimen about an axis perpendicular to the rolling plane of the specimen (corresponding to β or azimuthal angles in the pole figure) from a northeast to a southwest direction, and for 5° interval rotations of the specimen about axes in its own plane (corresponding to α or radial angles from the circumference toward the center of the pole figure) from 0° to 55° from the circumference. The high intensity maxima regions of the pole figures were determined more accurately by 1° or 2° α and β rotations.

Two sets of data were obtained on the heat treated specimens: 1—a decrease from the maximum intensity in the cold rolled condition to a minimum in the fully annealed condition, indicating the decrease in the amount of the old texture; and 2—an increase from minimum intensity in the cold rolled condition to a maximum in the annealed condition, indicating the amount of the new texture formed from the old. The orientation of the specimens with respect to the X-ray beam for these two experimental conditions will be apparent after presentation of the pole figure results in the next section. For heat treated specimens with an average

grain diameter greater than about 10 microns, the X-ray results were erratic, so that a device was used to scan a $\frac{1}{2} \times \frac{1}{4}$ in. area of the specimen. It was experimentally ascertained that satisfactory integrated intensity readings were obtained by using a 0.1° slit to define the X-ray source beam width and a 0.4° slit at the counter. A Soller slit was used to eliminate vertical divergence of the incident beam and

Fig. 4—Isothermal annealing curves for zirconium. Represents increasing X-ray intensity due to formation of annealing texture.

Fig. 5—Isothermal annealing curves for zirconium. Represents increasing X-ray intensity due to perfection of deformation texture and decreasing intensity due to formation of annealing texture.

another Soller slit was used between the 0.4° slit and the Geiger tube to minimize the vertical divergence of the diffracted beam.

Metallographic Techniques: The flat surfaces of the specimens were polished to about half thickness for metallographic examination. All micrographs were taken at 1000X or 1440X. Specimens with the smallest grain sizes had a highly oriented texture and the orientation differences between individual grains were so small that polarized light techniques were not satisfactory. An etching technique was developed in which the degree of surface staining of individual grains was sensitive to the slight existent orientation differences, and the grains were thus observable under bright field illumination. For those heat treated specimens in which some reorientation had occurred, longer immersion in the etchant produced an increasingly clearer delineation of the grain boundaries. The etching technique was as follows: 1—immerse specimen about 10 sec in a solution of 49 pct water, 49 pct nitric acid, 2 pct hydrofluoric acid to obtain a chemically polished surface; 2—etch in a solution of 75 pct glycerine, 23 pct nitric acid, 2 pct hydrofluoric acid for a time sufficient to give the desired staining. Because of the extremely small grain size of many of the specimens an accurate estimation of the grain size was impossible and has not been reported. Accurate grain sizes were obtained for most specimens by counting the grains (40 to 500) in a representative area of the micrographs.

Fig. 6—Isothermal annealing curves for zirconium. Solid lines represent data presented in Fig. 4 and dotted lines that presented in Fig. 5. Fig. 6A is schematic representation of full shape expected for all curves.

Vickers hardness measurements were made with a Tukon tester on the polished edges of all of the specimens using a 100 g load.

Experimental Results

Orientation Relationships: The prism plane $\{10\bar{1}0\}$ pole figure data give the most satisfactory and complete description of the angular relationships of the texture change when cold rolled zirconium is annealed, so that the pole figures for this reflection only have been included.

In previous qualitative texture determinations of zirconium¹⁷ no asymmetry of the pole figures for surface and for inside layers of straight rolled material was found. Likewise, in the present quantitative work no pole figure asymmetry was detected. The last 14 pct of the total 97 pct of reduction on the Sendzimir mill entailed a reversal of the rolling direction of the strip between passes.

A $\{10\bar{1}0\}$ pole figure of the 97 pct cold rolled zirconium is shown in Fig. 1. A pole figure for this material after 83 pct cold rolling differed only in the sharpness of the final texture. The qualitative pole figure determination in the previous investigation¹⁷ is in fundamental agreement with the present results. However, in Fig. 1 all of the six intensity maxima have been resolved and the average rotation of the prism poles about the rolling direction has been established as $36^\circ \pm 2^\circ$ (indicated by the cross symbols in Fig. 1) instead of the approximate 30° rotation previously reported. The small degree of scatter about the transverse direction and the greater degree of scatter about the rolling direction are apparent.

In Fig. 2 is shown the $\{10\bar{1}0\}$ pole figure for the cold rolled zirconium heated so as to produce an annealing texture. This result also is in general agreement with the previous qualitative texture determinations where it was indicated that the "recrystallization" texture could be derived from the cold rolled texture by a 30° rotation about the hexagonal pole figure axes. However, instead of six intensity maxima on the pole figure as previously found, there are six pairs of intensity maxima. One set of the pairs is indicated by triangular symbols and the other set by square symbols in Fig. 2. Annealing of 83 pct cold rolled zirconium produces similar results.

In Fig. 3 all points for the intensity maxima of the pole figures shown in Figs. 1 and 2 have been superimposed to demonstrate that the ideal annealing texture can be related to the ideal cold rolled texture by 20° or 40° rotations about hexagonal axial positions for the annealing texture. The heavy lines emanating from the cross symbols (cold rolled orientation) represent 20° rotations. In the one case 20° clockwise rotations give rise to the square symbols (all of which lie on a line rotated 36° about the rolling direction and counterclockwise 7° about the center point). Counterclockwise rotations of 20° give rise to the triangular symbols (all of which lie on a line rotated 36° about the rolling direction and counterclockwise 7° about the center point). Consequently the angle between any two points shown is about 20° .

Kinetics of Orientation Changes: The temperature dependent rate of change of the orientation has been determined by direct measurement of the intensity of the diffracted X-ray beam for all heat treated specimens. The intensity measured by the

Fig. 7 (left)—Zirconium cold rolled 97 pct and heated at 395°C for 24 min. Shows complete recrystallization "in situ" structure. Slight orientation differences between individual domains revealed by selective staining and bright field illumination. X1440. Area reduced approximately 75 pct for reproduction.

Fig. 8 (right)—Zirconium cold rolled 97 pct and heated at 395°C for 96 hr. Average domain diameter about 2 microns; approximately 55 pct of material has reoriented in the annealing texture. Grain boundary attack by etchant; bright field. X1440. Area reduced approximately 75 pct for reproduction.

Geiger counter located at the proper 2θ angle to receive the $\{10\bar{1}0\}$ diffracted beam was assumed to be proportional to the amount of the particular texture present. In Fig. 4 the rate of growth of an annealing texture from the cold rolled texture, determined by the method described, is shown. The specimens were situated in such a manner that the counting rates at point C on the pole figure of Fig. 3 were obtained. The intensity for this position was low in the cold rolled condition and a maximum in the fully annealed condition. Therefore, ordinate values are shown for both the measured counting rates and for the volume percentage of annealing texture formed. The latter values are calculated assuming that the rate of change of the volume of material in an orientation corresponding to that at point C is the same as that at every other point of the pole figure, and also that counting rate is proportional to the volume.

Counting rates measured for a specimen position corresponding to the cross symbol RD of Fig. 3, (prism planes perpendicular to the rolling direction) are shown in Fig. 5. An initial increase in the counting rate to a maximum at a rate dependent on time and temperature is apparent. The counting rates for the 98°C annealing are identical with the value for the as cold rolled zirconium, but the 198° and 295°C anneals indicate an increase in intensity, or degree of perfection, of the cold rolled texture. At still higher temperatures this maximum intensity is attained in shorter times before the intensity decrease due to gross reorientation takes place. The ordinate values for percentage of annealing texture in Fig. 5 were therefore chosen using as a zero the maximum value of the counting rates. Therefore, this ordinate does not apply to the initial increasing portions of any of the curves.

Corresponding curves for several of the temperatures plotted in Figs. 4 and 5 are replotted in Fig. 6. The dotted lines indicating the decrease in intensity of the cold rolled texture have been inverted so as to be comparable to the solid lines indicating the increase of the annealing texture. It is immediately apparent that there is no appreciable formation of the annealing texture during the period when an increase of sharpness of the cold rolling texture occurs. This plot shows further that not every volume of material leaving the old texture is immediately accounted for in the annealing texture, or else the two curves for a given temperature would superimpose.

It is suggested that if the full extent of the curves of Fig. 6 were known they would show a double continuous and successive S-shape as indicated

schematically in Fig. 6a. The solid 500°C curve of Fig. 6 illustrates the typical shape expected; the shape of the 600°C curves are an example of what the 500°C curves may look like in the third and succeeding cycles of time, and the 395°C curves illustrate what the 500°C curves may look like in cycles of time less than that shown. This is significant because it will be shown below that grain growth in zirconium occurs at times corresponding to the junction of the two sigmoids. The final increase in the rate of annealing texture formation associated with the second sigmoid of the solid curves is seen to occur also only after about 40 pct formation of the annealing texture regardless of the temperature of the annealing.

Metallographic Observations: Figs. 7 and 8 are micrographs of the two specimens annealed at 395°C for 24 min and 96 hr, respectively. The former corresponds to a stage in the curves of Fig. 5 at which the sharpening of the cold rolled texture has reached a maximum; the orientation differences between individual "grains" or domains (2 microns average diameter) are so small that their boundaries are not clearly delineated. In the case of the latter specimen, formation of the annealing texture is approximately 40 pct complete. For specimens heated for successively longer times orientation differences between the individual domains become more pronounced and the domain boundaries are attacked by heavier etching (Fig. 8) so that the grain size can then be accurately measured. The results of these measurements reproduced in Fig. 9 indicate that there is no appreciable grain growth during the annealing times employed at 395°C. This fact is also apparent in a qualitative way by direct comparison of Figs. 7 and 8. However, grain growth may be noted to occur at times and temperatures corresponding to formation of more than 40 pct of the annealing texture or corresponding to the second sigmoid in Fig. 4.

When domain growth does occur it can be expressed for all temperatures by the usual relation-

Fig. 9 — Isothermal domain growth curves for 97 pct cold rolled zirconium. Initiation time of domain growth corresponds to about 40 pct reorientation to the annealing texture.

Fig. 10—Hardness decrease curves for isothermal annealing of 97 pct cold rolled zirconium.

ship for isothermal grain growth in pure metals:

$$D = Kt^n$$

where D is the average domain diameter attained in time t ; K , a temperature dependent constant; and n , a constant. Evaluation of the slope of the lines in Fig. 9 gives a value of 0.35 for the constant n . The results of Dunkerley, Pledger, Damiano, and Fulton,¹⁸ for apparently essentially randomly oriented zirconium, in which the second phase was agglomerated in large particles at grain boundaries by annealing prior to the grain growth measurements, give a value of 0.39 for n . The results of Dunkerley et al. give an activation energy for grain growth of 55,000 cal per mol and the present results a value of about 70,000 cal per mol. The difference in activation energies may be caused by differences in purity of the materials and the degree of preferred orientation.

Hardness: The mechanical hardness data of the heat treated specimens are plotted as a function of time at temperature in Fig. 10, and as a function of temperature for 10, 100, and 1000 min of heating in Fig. 11. In Fig. 10 the short, vertical dashed lines indicate the time at the particular temperature for the completion of the sharpening of the cold rolled texture (peak of the curves of Fig. 5) and the upper, dashed horizontal line the average hardness level at which this process occurs. The lower set of vertical lines indicates the times at which domain growth commences (see Fig. 9) and the lower, horizontal dashed line the average hardness level at which such grain growth occurs. Thus, although the shapes of the curves in Fig. 11 appear to be similar to recrystallization curves involving a nucleation and growth process, it is quite apparent that the changes

Fig. 11—Hardness decrease curves for 10, 100, and 1000 min of isothermal annealing.

in hardness do not reflect the elementary processes occurring during the annealing of zirconium. For example, the samples appear to be completely recrystallized metallographically after only about 25 pct loss in initial hardness and lose about 75 pct of their initial hardness before grain growth occurs.

Discussion of Results

Formation of "Recrystallization in Situ" Texture: The first stages of recrystallization have been described in terms of the dislocation mechanism of polygonization^{5, 6} in which edge-type dislocations perpendicular to curved slip planes accumulate during annealing leaving a multitude of minute stress-free, unbent regions with essentially the same overall range of orientation as existed in the deformed crystal. With extended annealing certain subgrains grow at the expense of less favorably oriented subgrains and approach an orientation identical to the original orientation of the crystal. The first stage in this process has been termed polygonization and the second "recrystallization in situ"¹⁹ and this terminology has been adopted here.

Since the first stage of the polygonization mechanism is pictured as a fine scale subdivision of the undulated slip planes, a gross change of orientation of the material would not be expected. In the case of zirconium the phenomenon first observed is a gradual sharpening of the cold rolled texture. Only after this process is well along do domains of two microns average diameter appear metallographically and therefore the appearance of these domains is to be associated with recrystallization in situ rather than with the polygonization stage. This evidence suggests that some selective domain growth, corresponding to this maximum ideal orientation condition, has occurred. In the case of heavily cold worked aluminum²⁰⁻²² polygonization is partially complete at the deformation temperature with the formation of domains averaging 2 microns in diameter, and annealing causes a relatively stable state of coarse polygonization, or recrystallization in situ. Some unpublished results of Kulin and Bostrom²³ on electrical resistivity changes in severely deformed zirconium as a function of time at low temperatures indicate that processes occur at temperatures even lower than those used in this work, in fact even at room temperature. These processes are associated with the stages preceding recrystallization in situ and are presumably polygonization or other recovery mechanisms. The methods employed in the present investigation were not capable of detecting any processes preceding the stage known as recrystallization in situ.

Annealing Texture Formation Without Domain Growth: In heavily rolled polycrystalline aluminum, Beck and Hu¹² have metallographically observed domains about 2 microns in diameter after short time, low temperature annealing. These domains did not grow appreciably at the lower annealing temperatures, but at higher temperatures domain growth occurred and the slight orientation differences between domains became more clear cut and the pole figure scatter areas also became sharper. However, during domain growth, consumption of the polygonized domains by rapidly growing grains of an entirely different local orientation (cube texture) occurred.

With continued low temperature annealing of zirconium the X-ray data indicate a gross reorientation from the recrystallization in situ texture to the

Fig. 12—Changes in integrated X-ray intensity for 97 pct cold rolled zirconium caused by reorientation produced by annealing at 400°C. Measurements correspond to the path A-B-RD-B'-A' shown in Fig. 3.

new annealing texture. However, contrary to the case cited for aluminum, this reorientation takes place initially without any apparent grain growth.

Since no large grains are apparent in any of the micrographs of the annealed zirconium specimens (see Fig. 8), the growth mechanism by which the annealing texture is formed from the recrystallization in situ texture without an increase in average domain size is obscure. In order to ascertain if some larger grains actually were growing at the expense of smaller grains, a certain representative area of an enlargement of Fig. 8 (2 micron average grain diameter, 37 pct annealing texture) was cut up along the grain boundaries and each of the 138 pieces so produced was weighed on a balance. From these measurements average grain diameters were calculated and a frequency plot of grain diameters was made. The distribution was skewed toward small diameters and showed no definite evidence of discontinuous grain growth. The 338 grains in a micrograph of the specimen heated at 553°C for 180 min (5 micron average grain diameter, 55 pct annealing texture) gave similar results. Even for the fully annealed specimens with a complete annealing texture there is no evidence that discontinuous grain growth had occurred.

It is well known that impurities, as well as a high degree of preferred orientation, can inhibit grain growth. The period of no domain growth shown in Fig. 9 could be considered as an induction period during which the mitigating effect of impurities on domain boundary mobility is preponderant. Unfortunately, from the present experiments it is impossible to ascertain which factor, or combination of the factors, is responsible for the inhibition of domain growth. However, the present results for zirconium are believed to be similar to those of Beck and Hu,⁷ who observed no appreciable growth of the domains after recrystallization in situ of deformed aluminum even at temperatures sufficient to cause recrystallization to the cube texture. Dunkerley et al.¹⁸ observed similar induction periods in studies of grain growth in zirconium, but this behavior could be associated with the manner of impurity distribution alone since there was no evidence of a high degree of preferred orientation in their specimens.

A further attempt to understand the enigmatic gross reorientation without apparent domain growth involved the following experiment: A series of cold rolled specimens heated at 400°C were situated

with respect to the X-ray beam in such a manner that counting rate measurements were obtained at 1° or 2° intervals along the arc A-B-RD-B'-A' in Fig. 3 where A' and B' are positions similar to A and B on the arc. The slit system was identical with that used for the integrated intensity and pole figure measurements. From the results shown in Fig. 12 it is apparent that although the intensity increased near the ideal orientation for the 5 min heating time, it actually decreases at angles far from this orientation. In Fig. 13 are plotted the values:

$$100 \times \frac{I_t - I_{cr}}{I_{cr}}$$

for the various angles shown in Fig. 12 where I_t is the counting rate for a certain time of heating at 400°C at a given angle on the arc of Fig. 3, and I_{cr} is the corresponding value for the cold rolled condition. This is simply a representation of the percentage increase or decrease of the counting rate of a heated specimen with respect to the counting rate of a cold rolled specimen measured under identical

Fig. 13 — Quantitative changes in orientation shown in Fig. 12.

conditions. Polygonization alone would not be expected to account for the appreciable gross orientation sharpening apparent in Fig. 13 (for example, the Laue streaks for deformed single crystals have about the same range of orientation before and just after polygonization⁴). Again it would appear that in very short heating times (i.e. 5 min at 400°) some domains with orientations furthest removed from the ideal orientation are consumed by those closer in orientation to the ideal. Thus, the results of this experiment agree with those previously discussed.

Growth of a new orientation at an orientation corresponding to a maximum for the new texture formation is especially apparent in Fig. 13. Heating for 1839 min has caused about 33 pct of the volume of material to form in the new orientation even though the domain size is not appreciably greater than that for the specimen heated 25 min. A very large decrease in mechanical hardness was shown to occur during this stage of reorientation. The strain energy (hardness) is high after recrystallization in situ but low when domain growth starts. It must therefore be concluded that these domains are highly strained and that this strain energy is relieved only during a period of major change in crystal orientation un-

Fig. 14—Time for a given percentage decrease in X-ray intensity due to reorientation produced by isothermal annealing of 97 pct cold rolled zirconium.

accompanied by general nucleation or appreciable domain growth.

Annealing Texture Formation with Grain Growth: From the evidence that has been presented it is evident that the initial stages of annealing texture formation in zirconium are not explainable by the usual concepts of nucleation and growth since no change in grain size occurs. Even during the stage when grain growth does occur, the conventional nucleation and growth mechanism cannot explain the rate of annealing texture formation observed. If it did, the following equation derived by Johnson and Mehl,⁹ expressing the kinetics of general nucleation and growth of grains in a cold rolled matrix when heated so as to cause recrystallization, would be applicable:

$$f(t) = 1 - e^{-\frac{\pi}{8} NG^3 t^4}$$

where $f(t)$ is the fraction of the volume recrystallized in time t , and N and G are the rates of nucleation and growth, respectively. Straight lines are

obtained when $\log \log \frac{1}{1-f(t)}$ is plotted against \log

t ; the slope k is then equal to the power of t . For polyhedral growth in a highly deformed matrix where the rate of nucleation is great (mostly at the beginning of the transformation), a $k = 3$ dependence is predicted by this equation. Avrami¹⁰ has shown that for plate-like and acicular growth of grains a $k = 2$ and $k = 1$ dependence, respectively, would be expected. Decker and Harker¹⁸ have found in the case of primary recrystallization of copper, studied by the same X-ray method as employed in the present work, $4 > k > 3$ for the higher temperatures where polyhedral growth was suspected, and $3 > k > 2$ at lower temperatures where plate-like growth was suspected.

A similar plot of the present results for zirconium gives straight lines with a slope, or k value, of about 0.37 for all temperatures over ranges where at least 40 pct of the volume of the material has formed in the annealing texture; this is the range in which domain growth occurs. If activation energies are determined for this stage in the annealing process

by plotting \log time for given reorientation vs $1/T$ the curves of Fig. 14 are obtained. These curves indicate a continuous change in activation energy with increasing gross reorientation (and also increasing domain size). On the other hand, for copper and an iron-nickel alloy,^{18, 14} where the reoriented material is accounted for only by nucleation and growth of grains in the new orientation, a single activation energy has been found to express the total reorientation.

The almost twofold increase in activation energy from 40 to 90 pct reorientation is an indication that the environmental conditions during the reorientation process change continuously as reorientation occurs. The most obvious change in environmental condition occurring during this stage is domain growth. If the rate of annealing texture formation is assumed proportional to the grain size of the matrix, the equation given previously can be expressed as:

$$f(t) = 1 - e^{-ct^{3n}}$$

where c is a constant and n is the exponent expressing rate of grain growth in the equation $D = Kt^n$. Using the experimental value, $n = 0.35$, a power of t greater than unity would be expected; this is considerably different from the actual power of t obtained, namely 0.37.

In the case of copper¹⁸ and a nickel-iron alloy,¹⁴ the rate of change of the deformation textures and recrystallization textures are equal, but for zirconium a large difference in the two rates has been demonstrated (Fig. 6). In the former case, the recrystallized grains form only in the new texture with a time dependence consistent with the principles of primary recrystallization, but in zirconium the growth of grains in an annealing texture is microscopically indistinguishable from growth in the cold rolled texture.

Textures in Zirconium: The previous qualitative pole figures for the cold worked zirconium¹⁷ are in good agreement with those found in the present work as shown in Fig. 1. In the previous work it was shown that basal slip alone could not account for the cold rolled pole figure. Some recent work on titanium²⁴ indicates that basal slip is not operative in the deformation of single crystals of that material thus substantiating these previous observations on zirconium.

The pole figure for annealed zirconium shown in Fig. 2 is different from the qualitative pole figure previously reported¹⁷ in that the maxima are split into pairs, making an angle of approximately 20° with each other. It is suggested that, following Beck's theory,^{13, 25, 26} the grains formed on annealing may grow at an orientation showing maximum mismatch not only with the matrix but also with already formed neighboring grains of the new texture. Regarded from this point of view, the condition of maximum disorientation can be best met by effective 20° and/or 40° rotations. However, it might be expected that 60° cross rolled zirconium, which has a single texture, should also show 20°, 40° rotations, but recent work shows that only 30° rotations occur.

It was noted in the previous work on this subject¹⁷ that the hot rolling texture of zirconium is similar to the cold rolling texture rather than to the annealing texture. This same behavior has been noted in the

case of iron.²⁷ The observations described previously on recrystallization in situ afford a ready explanation for this fact. If it is assumed that during hot rolling recrystallization in situ occurs concomitant with the deformation, thus releasing part of the strain energy introduced by this working, then sufficient strain energy will not be stored in the matrix to permit the operation of further annealing processes, and a texture will result similar to the deformation texture rather than to the annealing texture.

Summary

1—Quantitative X-ray diffraction techniques have been used to (a)—determine $\{10\bar{1}0\}$ pole figures of 97 pct cold rolled zirconium, as rolled and as fully annealed, in order to establish the exact crystallographic relationships associated with the thermally activated texture changes that have been found to occur, and (b)—determine the rate of the reorientations for specimens heated for appropriate times at temperatures from 98° to 600°C.

2—Metallographic observations, hardness measurements, and other results have been correlated with the X-ray results and the following processes occurring during annealing have been identified: (a)—Polygonization may occur in zirconium during cold rolling or during the very first stages of heating. This polygonization is not accompanied by reorientation nor is it detectable metallographically. (b)—Recrystallization in situ (metallographic evidence of polygonization) occurs after annealing at relatively low temperatures and corresponds to a reorientation in which the ideal cold rolling texture is sharpened; this process may occur by selective growth of favorably oriented domains. (c)—Further annealing causes a complete reorientation corresponding to 20° or 40° rotations about $\{0001\}$ poles. This process occurs in two steps, the one at constant domain size, the latter accompanied by domain growth. Data have been presented to show that the processes do not occur by nucleation and growth of reoriented grains, nor by discontinuous growth of favorably oriented domains.

3—Activation energies for domain growth and for annealing reorientations have been calculated but are limited by conditions described in the text; a single activation energy cannot describe the reorientation process which is a further indication that a simple mechanism, such as nucleation and growth, does not govern the reorientation.

Acknowledgment

The work described in this paper was supported by AEC Contract AT-11-1-GEN-14. The authors wish to express gratitude to Raymond Boyle for the excellent quality of his considerable experimental assistance, G. F. Mechlin for guidance in the development of the X-ray techniques, and F. M. Cain and J. V. Miller for the development of the special metallographic techniques. Thanks are due W. A. Johnson, S. A. Kulin, and E. K. Halteman for advice and reading the manuscript.

Vanadium-Oxygen Solid Solutions

by A. U. Seybolt and H. T. Sumsion

The results of an investigation of vanadium-rich V-O solid solutions are presented, indicating the structure and lattice parameters of two solutions, α and β , and their approximate temperature-composition existence. The α solution is the terminal body-centered cubic one, and contains up to 3.2 atomic pct O. The β solution has an ordered body-centered tetragonal structure, is formed at 1270°C, and exists from about 15 to 22 atomic pct O. From the evidence available, the various phase boundaries have no appreciable temperature dependence. Evidence has been found for a polymorphic transformation in pure vanadium at 1550°C.

IN an earlier investigation¹ dealing with the preparation of pure vanadium by calcium reduction of the oxide, it was found that small amounts of oxygen drastically reduced the ductility of the metal. Because this effect was so marked, it was decided to make a study of the solubility of oxygen in solid vanadium. This report deals principally with this solubility and the nature of the phase relationships in the vanadium-rich region, particularly at temperatures below 1300°C. However, during the investigation enough data on the V-O system were obtained to make it appear worthwhile to present a tentative phase diagram up to the composition VO.

The only significant prior work found on this system are the contributions of Klemm and Grimm,² and Mathewson et al.³ Klemm and Grimm prepared a wide range of V-O compositions by powder techniques including the compositions VO_{0.1}, VO_{0.2}, VO_{0.3} and VO_{0.4} (9.1, 16.8, 23, and 28.6 atomic pct O, respectively). The first three compositions were found to consist of a body-centered tetragonal solid solution, while the last also showed lines of VO (NaCl structure). They found that the parameter c_0 increased and the parameter a_0 decreased with increasing concentration of oxygen. For their composition VO_{0.27}, or about 16.8 atomic pct O, they cite the values $a_0 = 2.948\text{\AA}$, $c_0 = 3.53\text{\AA}$, and $c/a = 1.2$. Klemm and Grimm made no attempt to determine the solid solubility limit nor to construct a phase diagram. They did, however, give some data on the homogeneity range of VO, and they proposed a

structure for the body-centered tetragonal solid solution; these points will be taken up later.

Materials and Preparation of Samples

The vanadium used in this investigation was prepared in the laboratory by the method previously mentioned.¹ A typical analysis is as follows: Fe, 0.007 pct; Si, 0.02; Ca, 0.06; C, 0.224; O₂, 0.044; N₂, 0.0017; H₂, 0.003; and V, 99.34 \pm 0.3 (assay). The vanadium assay is probably low by about the error given. The impurities total about 0.36 which, if subtracted from 100, gives a purity of about 99.6.

At the time material was being prepared for this work no suitable technique was available for melting vanadium without appreciable contamination. The procedure adopted therefore was to cut the calcium-reduced reguli into slices which were then rolled to strip about 0.025 in. thick for oxygen diffusion.

Pieces of rolled vanadium of approximately 0.025x $\frac{1}{4}$ x1 in. and weighing about 0.3 g were suspended in a vertical fused-silica tube which was part of an ordinary gas absorption apparatus. The silica tube was heated by an electric resistance-tube furnace which could be raised around the silica tube or lowered away from it as desired. This apparatus had no novel features which require detailed description. Other than the silica tube and furnace, it consisted of a glass system evacuated by a liquid nitrogen trapped mercury diffusion pump, a mercury-operated gas burette, a McLeod and a Pirani gage, and a mercury manometer. It was also equipped with suitably located stopcocks for isolating various parts of the system; the vacuum ordinarily attained was between 10⁻⁵ and 10⁻⁶ mm of mercury. Oxygen generated by decomposing MnO₂ was passed through anhydrous magnesium perchlorate before introducing it into the gas burette and thence to the absorption chamber.

A. U. SEYBOLT, Member AIME, formerly with Knolls Atomic Power Laboratory, is now associated with General Electric Research Laboratory, and H. T. SUMSION, Member AIME, is associated with Knolls Atomic Power Laboratory, General Electric Co., Schenectady.

Discussion on this paper, TP 3465E, may be sent, 2 copies, to AIME by April 1, 1953. Manuscript, Aug. 19, 1952. Los Angeles Meeting, February 1953.

Various V-O alloys up to about 20 atomic pct were prepared by vertically suspending the vanadium strips in the absorption apparatus at 900° to 1000°C and adding the oxygen gas a few cubic centimeters at a time. It was soon discovered that if a large quantity of gas was added at once, an oxide film was immediately formed on the surface of the metal which required a greater length of time for absorption into the sample than the same quantity of oxygen added a little at a time. After establishing the desired absorption temperature, about 4 cc of oxygen were added to the sample. This caused the pressure to rise to about 3 mm. When the pressure dropped again to the low micron region, it was evident that essentially all of the oxygen had been picked up by the specimen, either in solution or as a surface oxide or both. The time required for the sample to absorb this much oxygen was approximately 5 to 10 min. However, to give the oxygen a chance to diffuse throughout the sample, the sample was held for a period of at least 2 hr before adding the next increment of oxygen. About 12 cc of oxygen could be added per day, or in the neighborhood of 5 wt pct O₂ for a sample weighing 0.3 g. After the last oxygen addition, the sample was held for several hours at the diffusing temperature for further homogenization.

A diffusion constant D was calculated for oxygen diffusing into a vanadium sample at 900°C by making use of the observed drop in gas pressure as a function of time. Since a plot of grams of oxygen absorbed against the square root of time produced a straight line, the oxygen absorption was apparently diffusion-controlled. Then from the observed oxygen flux (grams absorbed into the sample per unit area per unit time) a diffusion constant was calculated where $D = 2 \times 10^{-7}$ sq cm per sec. This value must be regarded as a tentative one until a more precise experiment is carried out.

Samples containing 20 atomic pct O or more were prepared by arc melting vanadium and V₂O₅ in an argon atmosphere using an arc-melting furnace ordinarily utilized for the preparation of zirconium and titanium alloys. While this apparatus was satisfactory for preparing V-O alloys, it was not useful for melting pure vanadium because the melting atmosphere was not under sufficiently good control to avoid vanadium embrittlement by the absorption of small quantities of oxygen.

Many of the alloys were analyzed by vacuum fusion for oxygen content but it was obvious that the synthesis was more accurate than analysis. With oxygen contents of less than about 10 atomic pct, agreement between the amount of oxygen added volumetrically and the amount found gravimetrically was excellent. However, with higher oxygen contents there was usually considerable variance between the two, presumably because of cumulative errors in reading a large number of small volumes in the gas burette. In any case, the gain in weight was always used as the method of determining the oxygen present in the samples. Naturally, this method could not be used with the arc-melted samples; here it was necessary to rely on a chemical analysis for vanadium, taking oxygen by difference. Vacuum-fusion analyses could not be used with the oxygen-rich samples as the volume of gas from even a very small sample was too large to be collected and stored.

The diffusion method of sample preparation worked very satisfactorily, and there was no indication that

Fig. 1—Vickers hardness number vs atomic percentage of oxygen.

significant concentration gradients were present from the surface inward. Microhardness measurements taken across the thickness of samples and the general reproducibility of test results indicated satisfactory homogeneity. Any sample which showed a surface tarnish after the diffusion preparation was discarded as regards estimating composition. Invariably, however, samples prepared in the standard manner described above emerged from the gas absorption apparatus with a clean surface.

Hardness of V-O Alloys

Fig. 1 shows a plot of Vickers hardness number vs atomic pct O for alloys quenched from 900°C. Slow cooling the alloys instead of quenching them made only a few points difference (lower) in hardness. Vanadium containing more than approximately 0.05 wt pct O (about 0.15 atomic pct) is relatively unworkable or partially brittle at room temperature, but metal containing less than this amount of oxygen is very ductile unless otherwise contaminated.

X-Ray Diffraction Measurements

After examining a few 5.73 cm diam Debye X-ray diffraction films of various V-O alloys, it was clear that many of the alloys were body-centered tetragonal as claimed by Klemm and Grimm.² Also, a trend could be established in which the lattice parameter ratio c/a increased with increasing oxygen content, likewise in agreement with the findings of these authors.

While the X-ray diffraction method was very valuable in the investigation since considerable information was obtained, it turned out to be a tedious and inefficient technique because of the poor quality of films obtained. The only suitable X-ray targets for back-reflection lines were copper and nickel, with copper more generally satisfactory as regards line position for precision measurements of parameters. Unfortunately, copper and nickel radiation cause a large amount of vanadium fluorescent radiation, blackening the film and causing poor contrast. From theoretical considerations, the only target materials which would be free of this defect are titanium, chromium, or metals of lower atomic weight than titanium. A titanium target was not available. Chromium radiation produced no fluorescence and

Fig. 2—Debye-Scherrer films of various V-O alloys. (Cr-K α radiation).

gave very good lines, but yielded an insufficient number of lines in the back-reflection region; it was used only for qualitative data, see Fig. 2.

Body-Centered Cubic Measurements: Parameters of body-centered cubic alloys were measured with a 12 cm diam back-reflection focusing camera, using lines of the (321) planes. Film shrinkage was corrected from measurements on fiducial marks. The parameters thus obtained and shown in Table I are considered to be accurate to at least 0.0005Å. Extrapolation methods could not be used with the V-O alloys because of too few lines, but the parameters of the two pure vanadium samples were obtained by 90° extrapolation using Cohen's method.⁴

The calcium-reduced metal used in the investigation gave $a_o = 3.0278 \pm 0.0001\text{Å}$ from an extrapolation of five points, and high purity iodide metal from Battelle Memorial Institute gave $a_o = 3.0258 \pm 0.0001\text{Å}$ on a comparable extrapolation but using only three back-reflection lines. This metal was prepared by the method of Nash et al.⁵ and has the following typical analysis: Fe, 0.07 pct; Al, 0.005; Si, 0.002; Cr, 0.002; O, 0.012; N, 0.008; and H, 0.005. The less precise values from measurement of the (321) planes as described above are reported in Table I in order to show values comparable to the V-O alloys.

Fig. 3—Lattice parameter ratio c/a vs atomic percentage of oxygen.

Body-Centered Tetragonal Measurements: Most measurements were made with the precision camera; but occasionally the lines were too faint, and recourse was had to the small (5.73 cm diam) Debye camera. In either case, measurements were made on the (321) and (312) lines. Data in Table I for body-centered tetragonal structures are reported to the third decimal place with the probable error less than 0.002Å.

In a few cases where Debye camera measurements are reported, the Straumanis technique⁶ of compensating for film shrinkage was followed.

All films were read on an illuminator equipped with a vernier scale reading directly to 0.02 mm.

Heat Treatments: An annealing temperature of 600°C was used with all specimens as a standard low temperature treatment. The lattice parameters obtained at this temperature level were compared to those after quenching at higher temperatures to find out if the oxygen solubility was a function of temperature. It was standard practice to seal off the -200 mesh powder in a vanadium foil-lined, evacuated, fused-silica tube. The silica tube was suspended in a vertical tube furnace, and at the end of the heat treatment was thrust under water for a quench. While a faster quench could have been obtained by crushing the silica tube under water,

Fig. 4—Lattice parameter of body-centered cubic α phase as a function of oxygen content.

this was not done because of danger of contaminating the vanadium.

By plotting c/a vs atomic pct O for several heat treatments, the graph shown in Fig. 3 was obtained. Since the parameter measurements were about the same after quenching, from various temperature levels, there seemed to be no reason not to show all the data on a single curve. The location of line A-B was determined by plotting the lattice parameter of dilute cubic alloys against concentration, see Fig. 4. Figs. 3 and 4 are interpreted as follows: Oxygen dissolves in solid vanadium up to 3.2 atomic pct without altering the basic structure, but causing a linear lattice expansion of about 0.66 pct. Beyond this point a body-centered tetragonal phase makes its appearance, creating a two-phase region up to 14.7 atomic pct O. No change in c/a occurs during the two-phase interval since the compositions of the two phases (α and β) are fixed.

After passing point C in Fig. 3, the α phase disappears leaving pure β . The c/a ratio for the β solid solution increases with oxygen content, up to point D, the solubility limit of oxygen in the β phase. Further additions of oxygen result in the appearance of VO, a compound of established structure (NaCl) and which according to Klemm and Grimm,² has a homogeneity range from about 47.4 to 56.5 atomic pct O.

Because of lack of precise reproducibility, there was as much lattice parameter variation between different samples of similar oxygen content as in the same sample heat treated at different tempera-

tures. All that can be stated at present regarding the effect of temperature is that if the composition limits of the α and β phases vary with temperature, the variation is apparently not large.

Structure of the Beta Phase

Klemm and Grimm² postulated the structure shown in Fig. 5 for the body-centered tetragonal solid solution. It is interesting to note that this is identical to the structure suggested by Jack⁷ for nitrogen martensite found in the Fe-N system.

Because of the availability today of neutron diffraction as a structure tool, it was considered desirable to locate the oxygen atoms in the β phase directly instead of deducing their position by displacements of the metal atoms. This test was carried out with the cooperation of Dr. E. O. Wollan at Oak Ridge National Laboratory. The neutron diffraction pattern obtained for the oxygen atoms in a 21 atomic pct alloy supported the structure deduced by Klemm and Grimm, Fig. 5, and by Jack for the nitrogen atoms in nitrogen martensite. The details of this investigation will be reported elsewhere.

From the configuration of the atoms in Fig. 5 it can be seen that there are two vanadium atoms and two oxygen atoms per unit cell. The saturated solid solution, if entirely composed of this structure, would reach VO or contain 50 atomic pct O. However, it has been shown in Fig. 3 that the β phase does not reach this concentration but is saturated at approximately 21.8 atomic pct O. Since 50 atomic pct corresponds to two oxygen atoms per unit cell, there is 2/50 or 0.04 oxygen atoms per unit cell for each atomic percentage of oxygen. Hence, multiplying the concentration of an alloy in atomic percentage by 0.04 gives the fractional number of oxygen atoms per unit cell.

In Fig. 6 are plotted the parameters a_0 and c_0 in the range from 14.7 atomic pct for the unsaturated

Fig. 5—Structure of body-centered tetragonal V-O solid solution (all interstitial positions filled).

β solution to 21.8 atomic pct for the saturated solution. From the intersections of the linear plot of the two parameters, normalized a_0 and c_0 values may be read off for these two concentration limits, see Table II. By subtracting the unit cell volume of pure vanadium from the unit cell volume of the two β phase concentrations mentioned above, the increase in average unit cell size may be computed (col. 6 in Table II). The volume occupied by an average oxygen atom may then be approximated by dividing the increase in cell volume by the number of oxygen atoms in that cell.

By assuming that the cell volume increase per oxygen atom is entirely occupied by the atom, an upper limit to the size of the oxygen atom may be calculated by equating the volume to $4/3 \pi r^3$ (volume of a sphere) and solving for r . The radii determined in this way for the unsaturated and saturated β solutions are given in Table II. Obviously, this results in too large an oxygen radius since the oxygen atoms do not fully occupy the extra cell space they create.

Another approach is to calculate the radius of the largest circle in the center of a (001) face using a_0

Fig. 6—Effect of oxygen concentration on the lattice parameters of the body-centered tetragonal (β) solid solution.

$= 2.94\text{\AA}$ for the saturated β solid solution and 1.31\AA for radius of the vanadium atom. The solution for this gives an oxygen radius of 0.77\AA , a value which agrees reasonably well with the covalent bond radius for oxygen (0.74\AA) suggested by Schomaker and Stevenson.⁸ The unit cell expansion from the volume of the original vanadium to that of the unsaturated β phase is 5.04 pct, while the corresponding expansion of the saturated β phase is 9.06 pct.

Investigation of Phase Equilibria by Other Methods

Other techniques used in this investigation include electrical resistivity, thermal analysis, thermoelectric effect, microscopic examination, and hydrogen equilibrium. Neither electrical resistivity nor thermal analysis showed any property versus temperature discontinuities in the region where these methods were used (up to 8 atomic pct O and 1200°C). The electrical resistivity method was capable of easily detecting a 1 pct change in this property.

Microstructures: While the microstructures observed in the vanadium alloys were very interesting and instructive in a qualitative sense, it was not feasible to use metallographic evidence in locating phase boundaries. Fig. 7 shows the structure of the vanadium starting material; the particles of constituent visible are VC or V_2C . Fig. 8 shows how 5.7 atomic pct O produces "strain markings" which are caused by the presence of the β phase. Fig. 9 is very typical of alloys in the region near 6 to 7 atomic pct O; here again, more clearly visible bands are apparently deformation markings which have been formed by some cooperative slipping or shearing of the parent α lattice during partial transformation to β . Fig. 10 is characteristic of alloys from the central $\alpha + \beta$ region to the saturation limit of β . At first glance, it resembles a fine-grained austenitic

stainless steel, profusely twinned. Closer inspection indicates some differences and these are: 1—the "twin" bands are not very uniform in width, and 2—there are many areas of extremely fine lamellae, some of which cannot be resolved by the most powerful objective of the light microscope. Fig. 11 shows a particularly clear example of the lamellae in which are seen bands resembling twins, but which contain a lamellar structure, originating possibly by a double shearing action as described by Bowles et al.⁹ for the case of certain In-Th alloys.

It cannot be argued that the alloy of Fig. 11 contains $\alpha + \beta$ since the X-ray evidence is clear that it consists entirely of the β phase. Hence, there is a continuum of metallographic structures from the $\alpha + \beta$ region through the β region such that it cannot be determined by this method whether the alloy contains two phases or one phase. Metallographic structures of similar appearance have been reported by Newkirk et al.,¹⁰ Guttman,¹¹ and Lipson et al.¹²

It is interesting to note that Fig. 12, which shows the structure of an arc melted 21 atomic pct alloy, does not exhibit any banding or lamellae. This suggests that the lamellae, since they are only present in the samples prepared by diffusion, originate during oxygen diffusion. Obviously, with the average unit cell increasing in volume by 5 to 9 pct in the β phase, large amounts of lattice strain are required to create a stable nucleus of the β phase. The creation of nuclei of the β phase might be expected to require a cooperative shearing action in order to produce the displacements necessary to make room for the large β lattice, hence, the bands and lamellae. When the vanadium alloy is converted completely to the β phase, as in Fig. 11, the deformation bands originating during transformation remain even after transformation is complete.

The situation with the arc-melted alloy is quite different as here the β phase originates from the reaction $\alpha + \text{VO} \rightarrow \beta$ at 1270°C (see later). Since this reaction occurs at a comparatively high temperature, there must be considerable stress relaxation, with apparently insufficient stress to cause the deformation markings, or lamellae, during transformation. However, many cracks are observed, which presumably originated at some lower temperature during cooling.

Figs. 13 and 14 show structures observed in alloys containing more than 21.8 atomic pct O (26.2 and 25.9 , respectively). These alloys, like that of Fig. 12, were prepared by arc melting. All of the arc-melted alloys were given various heat treatments from 1000° to 1400°C , but with only minor effects on the microstructure; mainly a somewhat different percentage distribution of the two phases ($\beta + \text{VO}$). The important thing about Figs. 13 and 14 is the Widmanstätten structure in certain areas which suggests the presence of a eutectoid transformation at some elevated temperature. No attempt was made to locate the coordinates of the eutectoid nonvariant

Table II. Geometry of the Unsaturated and Saturated Beta Phase and Approximate Size of the Oxygen Atom

	Atomic Pct Oxygen	a_0	c_0	Unit Cell Volume, \AA^3	Increase in Cell Size, \AA^3 Due to Oxygen	Number of Oxygen Atoms per Cell	Volume per Oxygen Atom, \AA^3	Radius of Oxygen Atom, \AA

horizontal, nor to identify the decomposing solid solution, as this was considered outside the scope of this investigation.

Hydrogen Equilibrium: McQuillan⁹ has demonstrated that phase transitions may be detected in metals having a fairly high hydrogen solubility by measuring the equilibrium pressure of hydrogen over the alloy as a function of temperature.

The amount of hydrogen necessary for such

measurements is very small, usually the order of 0.1 atomic pct; the pressure is in the micron range. McQuillan has shown also that if the log of hydrogen pressure is plotted against $1/T_K$, a straight line results as long as the alloy contains one phase, or as long as the relative proportion of two phases remains fixed. However, in going from a single-phase region to a two-phase region, or vice versa, or from one two-phase region to another two-phase region,

Fig. 15—Hydrogen pressure $-1/T_K$ plot for two V-O alloys.

a discontinuity in the $\log p$ vs $1/T_K$ plot results because of differences in hydrogen solubility in one or more phases.

An advantage of this method in investigating a system like V-O is that it does not involve mechanically attaching a thermocouple or potential leads, etc., to the brittle specimens. The apparatus used consisted of a mullite tube closed at one end about $\frac{1}{4}$ in. ID x 8 in. long attached to the glass vacuum system previously mentioned. Adjacent to the mullite tube was a Distillation Products Pirani gage for measuring the hydrogen pressure. A small platinum-wound resistance furnace was used to heat the sample tube up to 1450°C .

Procedure for Making a Hydrogen Pressure Run: The samples used contained 7.6 and 25 atomic pct O and weighed about 1 to 4 g. After dropping the samples into the mullite tube which had been previously degassed at a temperature higher than that planned for the hydrogen equilibrium run, the sample tube was pumped down to about 10^{-5} to 10^{-6} mm of mercury. The samples were heated to about 1000°C and thoroughly degassed at this level, after which about 1 cc of dry hydrogen was introduced into the gas absorption apparatus open to the mullite tube. After waiting a few moments, the pressure of hydrogen (at first too high to read on the Pirani gage) was reduced to about 5 microns. At this level a stopcock was closed which isolated the sample tube and Pirani gage from the vacuum system. Pressure-temperature readings were taken every 10°C or thereabouts, using a calibrated Pt-Pt-Rh thermocouple.

Several runs were made with both alloys with the result that a single arrest was found at $1270^\circ \pm 10^\circ\text{C}$, see Fig. 15. Apparently the nonvariant horizontal referred to above occurs at this level from at least 7.6 to 25 atomic pct O. Cooling curves were attempted a few times, but without success; the pressure failed to fall in a reproducible way and yielded data of no value. This may have been caused by a mullite-sample reaction, but there was no visible evidence of such a reaction; the samples always dropped out of the tube clean and bright and no discoloration was evident inside the tube. However, since several heating curves all gave the same

value of $1270^\circ \pm 10^\circ\text{C}$, there seems to be no doubt that: 1—there is a reaction at this level, and 2—that this temperature within the error mentioned is correct.

Tentative V-VO Phase Diagram: The phase diagram, Fig. 16, was drawn from the following evidence: X-ray diffraction measurements clearly showed the presence of the α , $\alpha + \beta$, β , and $\beta + \text{VO}$ fields as indicated previously. The limits of these phase fields have also been described, and evidence has been cited for believing that the phase boundaries are essentially vertical. The homogeneity range of VO (47.4 to 56.5 atomic pct O) has been taken from the work of Klemm and Grimm,² and it was assumed that its phase boundaries, as in the other phases, are vertical.

A few optical pyrometer liquidus and solidus points were determined for alloys containing 21, 26, and 48 atomic pct O with the results shown as circles. VO apparently melts congruently in the vicinity of 1900°C . These preliminary results must be assumed to be only semiquantitative, but they suggest a peritectic reaction and such a relation fits in with the deduced existence of the γ phase (see below). Also, no metallurgical evidence for a eutectic was found.

The β phase apparently forms by a peritectoid reaction at 1270°C : $\alpha + \text{VO} \rightarrow \beta$ as already suggested. The nonvariant horizontal is drawn dotted beyond the 25.5 atomic percentage region to VO since no data were obtained in that region.

Since metallographic evidence suggested the existence of a eutectoid reaction, the eutectoid horizontal must evidently be at some temperature above 1270°C . It is also clear that there must be some solid solution fairly rich in oxygen which breaks down to form the eutectoid. Hence, a second terminal solid solution (γ) extending for a considerable distance into the diagram was postulated. However, before this hypothesis could be seriously considered, it was necessary to show that pure vanadium undergoes a polymorphic transformation at some high tem-

Fig. 16—Tentative V-VO phase diagram.

Fig. 17—Electromotive force of V-Mo thermocouple as a function of temperature.

perature, probably above 1400°C. The melting point of vanadium was taken from Adenstedt et al.¹⁴

Evidence for such a transformation at 1550°C is presented in the next section, but no information was obtained on the structure of the new phase.

The location of the eutectoid horizontal at 1450°C is purely arbitrary. The suggested eutectoid point at 40 atomic pct O was estimated from the appearance of microstructures of annealed V-O alloys containing about 25 atomic pct O.

High Temperature Polymorphic Transformation in Pure Vanadium

After considering various possible experimental methods, it appeared that the measurement of the electromotive force generated by a V-Mo or V-W thermocouple as a function of temperature would be experimentally simple and sufficiently sensitive.

Accordingly, two preliminary experiments were made in a high-frequency heated vacuum furnace in which a V-Mo thermocouple junction was pressed into a slot cut in the side of a ½ in. cube of molybdenum. By sighting an optical pyrometer on the molybdenum block and simultaneously reading the thermocouple electromotive force, it was possible to obtain a plot which showed some evidence of an arrest in the neighborhood of 1540°C. Similarly, a V-W thermocouple gave an unmistakable arrest at 1520°C.

Since there was a strong indication of a vanadium transformation, a third run was made in a tungsten resistance furnace using a helium atmosphere and a V-Mo thermocouple. For temperature measurements a Pt-Pt-Rh thermocouple was used which had been previously calibrated at the melting point of electrolytic iron, 1535°C. The data of this run are plotted in Fig. 17. This curve shows clear evidence of a polymorphic transformation in vanadium at about 1550° ± 10°C.

Summary and Conclusions

The results of an investigation of vanadium-rich V-O solid solutions are presented, indicating the structure and lattice parameters of two solutions, α and β , and their approximate temperature-composition existence. The α solution is the terminal body-centered cubic one, and contains up to 3.2 atomic pct O. The β solution has an ordered body-centered tetragonal structure, is formed at 1270°C, and exists from about 15 to 22 atomic pct O. From the evidence available, the various phase boundaries have no appreciable temperature dependence.

A tentative phase diagram is presented from V to VO, but the region above 1270°C is largely speculative. However, there is enough information available about the behavior at these higher temperatures to make it worth presenting as a suggestion to future investigators.

Evidence has been found for a polymorphic transformation in pure vanadium at 1550°C.

Acknowledgments

The assistance and advice of many of our colleagues are gratefully acknowledged. In particular, we wish to mention the help of John Duffy who prepared the samples and assisted with many of the experiments.

Cold-Rolling and Annealing Textures of Molybdenum Single Crystals

by N. K. Chen and R. Maddin

THE textures of straight-rolled and of cross-rolled molybdenum were first determined with the aid of pole figures by Custers and Riemersma.¹ These authors have shown that for straight-rolling, the main texture was (100) [011] with a considerable spread about the rolling direction. After cross-rolling a second texture was obtained in which there was a [111] axis perpendicular to the rolling plane, possessing a rotary symmetry. Recently Semchyshen and Timmons² in their study of preferred orientation of arc-cast molybdenum sheet obtained similar pole figures. In these two investigations, polycrystalline materials were used. In the main, the textures of molybdenum in these cases are qualitatively consistent with rolling textures of other body-centered cubic metals, such as iron and Fe-Si alloys.³

In the present investigation, single crystals of molybdenum were deformed by rolling with respect to specific crystallographic planes and directions. Since the deformation textures of polycrystalline aggregates have been related intimately to the behavior of individual grains,⁴ a study of possible correlations of final textures with respect to the initial orientations of the single crystals might conceivably lead to a better understanding of the textures. Annealing treatments were carried out after deformation in order to study the recrystallization characteristics as well as the recrystallization texture.

Rolling of Single Crystals

Single crystals of molybdenum (about $\frac{1}{8}$ in. in diam \times 1-in. long), grown by the method previously described,⁵ were cold-rolled without intermediate anneals. Except for specimens MR-1 and MR-2, which were rolled at random in the preliminary test in order to find a proper rate of reduction, all other specimens were carefully documented as to their respective orientation before deformation by means of X-ray Laue back-reflection methods. A stereographic projection was constructed from which it was possible to determine a particular plane and direction to be considered for rolling. Parallel flat surfaces were then polished metallographically with respect to a reference scratch on the specimen which was mounted in sealing wax. These flat surfaces contained the plane chosen for rolling. After etching, a Laue back-reflection photograph was again made of one of the flat surfaces to determine the

Table I. Summary of Rolling Results of Molybdenum Single Crystals

Specimen No.	Initial Thickness, In.	Final Thickness, In.	Reduction in Thickness, Pct	Remarks
MR-1	0.082	0.036	56.1	Deformed rapidly; specimen cracked
MR-2	0.092	0.004	95	Small amount of polycrystals present. Cracking occurred
MR-3	0.089	0.0035	96	Polycrystalline section contained in single crystal rolled to 90 pct
MR-4	0.093	0.003	96.8	
MR-5	0.095	0.002	97.9	
MR-6	0.105	0.007	93.3	
MR-7	0.087	0.005	94.3	Severe cracking; cross rolled
MR-8	0.099	0.004	96	
MR-9	0.088	0.004	95.6	
MR-10	0.084	0.011	87	
MR-11	0.087	0.006	93.2	Cross rolled
MR-12	0.082	0.0015	98.2	Cross rolled
MR-14	0.092	0.003	96.8	Compression rolled
MR-15	0.077	0.003	96.2	Compression rolled
MR-16	0.090	0.0015	98.4	Compression rolled

exact plane of rolling. The initial orientations of all the specimens (specified by two elements for each crystal, direction of rolling and the pole of the rolling plane) are summarized in Fig. 1.

The specimens were mounted in plasticene between two hardened Si-Fe plates. The sandwich was then rolled down, keeping the direction constant in the case of straight-rolling. In cross-rolling (MR-10, MR-11, and MR-12) the sandwich was rotated 90° after each pass so that every first and third pass contained the same rolling direction. Specimens MR-14, MR-15, and MR-16 were compression-rolled following the manner of Barrett.⁶ In these cases the direction of the sandwich through the rolls was changed by 3° to 5° for each pass until the specimens were rolled to the desired reduction in thickness. It was found that if extreme care was exercised in rolling, i. e., the amount of deformation per pass was extremely small, the specimens could be rolled to a large reduction in thickness. The rate of reduction used, with a single exception of MR-1, was generally 0.001 in. per 10 passes. Thus, it took about 800 passes to reduce a specimen to a final reduction in thickness of 87 to 98 pct. The results of rolling are shown in Table I.

Cold-Rolling Textures

The final orientations were determined by the conventional Laue transmission method,⁸ using molybdenum radiation, with or without a zirconium filter. Pole figures were plotted from {110} and {200} reflections in which three degrees of intensity—heavy, medium, and light—were determined visually.

Three main types of textures have been observed from the deformed single crystals. These are: 1—a

Fig. 1—Initial orientations of molybdenum single crystals used before rolling. Solid circle, crystals developed texture (001) [100]; open circle, crystals developed texture (001) [110]; double circle, crystals developed texture (111) [112]; x, crystals compression-rolled, texture [001].

(001) [110], 2—a (111) [112], and 3—a (001) [100]. A pole figure representing the first type (MR-4 and MR-6) is shown in Fig. 2. It is seen that the main texture is (001) [110], with a spread of 15° about the rolling direction. This type of preferred orientation has generally been observed as the rolling texture of most body-centered cubic metals. A pole figure representing the second type is shown in Fig. 3 for specimen MR-5. The average orientation can be described as a (111) [112] texture, with a spread of 10° about the sheet normal. A minor component, (001) [100], may be noted. A similar preferred orientation, but with a greater spread about the pole

Fig. 2—(110) pole figure for rolled molybdenum single crystal MR-4. Ideal orientations indicated as follows: A, (100) [011]; B, (115) [110]; F, (111) [112].

of the rolling plane, is shown in Fig. 4 for MR-12. A component representing a (001) [100] texture can also be noted.

The third type of texture, (001) [100], has been consistently observed in the present investigation for crystals whose initial orientation had a (001) near the rolling plane and [100] near the rolling direction. Figs. 5 and 6 are pole figures representing this texture. It may be seen that this "cube" texture has a greater spread about the pole of the rolling plane than about both the rolling and transverse directions. The significant point is that there is no [110] in the rolling direction which has generally been observed as the rolling direction of body-centered cubic metals. To check more sensitively the existence of the predominant [100] direction, an X-ray photogram, Fig. 7, was taken with the specimen tilted 13° to the X-ray beam ($\theta = 13.1^\circ$ is the Bragg angle for (200) reflection by molybdenum $K\alpha$ radiation). It is seen, Fig. 7, that the maximum intensity of (200) was obtained and, in addition, all other intensities testify to the existence of [100] as

Fig. 3—(110) pole figure for rolled molybdenum single crystal MR-5. Ideal orientations indicated as follows: F, (111) [112]; G, (100) [001].

the rolling direction. These additional photograms were felt necessary, since the existence of a "cube" texture in a deformed body-centered cubic metal has not previously been reported.

The texture resulting from compression rolling can best be described as a [100] fiber coinciding with the compression axis. However, it was also observed that the texture in the rolling plane is not completely random, but contains a cube component parallel to the initial length axis of the specimen. This is considered to be due to the incapability of uniform flow in all directions. Fig. 8 points to this conclusion.

Annealing Textures

The deformed specimens were annealed in argon purified with titanium at a temperature of 950°C for 1 hr. The specimens showed no recrystallization after this treatment as judged by numerous X-ray photograms. A second heat treatment for 3 hr at 1080°C also showed no recrystallization. However, annealing for 14 min at 1350°C resulted in complete recrystallization. The textures after this latter treat-

Fig. 4—(110) pole figure for rolled molybdenum single crystal MR-12. Ideal orientations indicated as follows: F, (111) $[11\bar{2}]$; G, (100) $[001]$.

ment are as follows: Those specimens having a deformed texture described as (001) $[100]$ maintained this texture after recrystallization; those specimens having a deformed texture described as (111) $[11\bar{2}]$ also retained this texture upon recrystallization. However, those specimens with (001) $[110]$ as the deformation texture changed into one upon recrystallization which can best be described as (001) in the rolling plane with a direction about 20° from the $[110]$. A pole figure representing this recrystallization texture is shown in Fig. 9.

Discussion of Results

The "cube" texture in the present results is quite different from what has been observed as the rolling

texture of body-centered cubic metals as reported in the literature.¹⁻⁴ Since $[111]$ is the slip direction such a texture is difficult to explain by the existing theories^{7,8} owing to the fact that a $[100]$ direction would not be a stable end position as the direction of rolling.⁷ A possible explanation must be sought from the initial orientations, chosen as the rolling plane and the rolling direction. It is seen from Fig. 1 that all specimens (MR-3, MR-9, MR-10, MR-11, MR-7, and MR-8) which had their rolling direction and pole of the rolling plane very close, within 10° , to a cube axis developed an approximately "cube" texture after rolling, Figs. 5 and 6. This seems to indicate that although a $[100]$ direction should not be a stable end position as a rolling direction during ordinary rolling processes, it could be made metastable in the present case of extremely slow reduction of a single crystal with an initial "cube" orientation.

It is interesting to note that in the rolling of single crystals of iron with the initial rolling direction near $[001]$, Barrett and Levenson⁴ did not observe the

Fig. 6—(110) pole figure for rolled molybdenum single crystal MR-8, and also other crystals with their initial orientations near (100) $[001]$ position. The main orientation is a cube texture; G, (100) $[001]$ with a spread about the normal direction.

existence of a "cube" texture. However, their rolling procedure consisted of reducing the crystals to 82 to 97 pct reduction in thickness in 20 to 40 passes, while in the present case, more than 800 passes were used for the same final reductions. It should also be noted that the theory developed by Decker and Harker⁹ would account for the existence of a "cube" rolling texture in the following manner: While their theory suggests that a grain would keep its initial orientation if: "(1) the slip planes are symmetrical with respect to the normal and transverse plane and, (2) the slip directions nearest the planes of greatest shear stress lie in the plane containing the rolling direction and the normal to the rolling plane," the second condition should be modified to read: "the slip directions nearest the planes of greatest shear stress are symmetrical with respect to the normal transverse plane."¹⁰ It would seem that the conditions modified by Decker are satisfied for crystals having an initial cube orientation. Further emphasis as to the applicability of this theory would appear

Fig. 5—(110) pole figure for rolled molybdenum single crystal MR-8, and also other crystals with their initial orientations near (100) $[001]$ position. The main orientation is a cube texture, G (100) $[001]$, with a spread about the normal direction. A, B, C, D, E, and F are ideal orientations generally observed for body-centered cubic materials and molybdenum single crystals whose initial orientations are far from (100) $[001]$ position.

to be obtained here since the "cube" texture was retained after recrystallization.

The textures (001) [011] and (111) [$\bar{1}1\bar{2}$] can be explained on the same basis of initial orientation difference as proposed by Barrett and Levenson.⁴ It can be seen in Fig. 1 that for crystals MR-4, MR-5, MR-6, and MR-12 the rolling plane and direction were both distant from a starting (100) [001] position. The development of the preferred orientation in the cases of MR-4 and MR-6 would thus involve mainly a rotation of their initial normal directions toward W_1 , and their initial rolling directions toward I and II, respectively. For crystals MR-5 and MR-12, the rotations would be mainly the movement of the initial normal directions toward D and their rolling directions toward E and F , respectively. Since a co-existence of the two textures was observed in these cases, varying only in their relative amount, fragmentation into deformation bands might be expected. However, no metallographic evidence could be observed.

It should be noted that MR-10, MR-11, and MR-12 were cross-rolled. Since MR-10 and MR-11 had both their initial rolling and transverse direction almost

Fig. 7—Pattern for rolled molybdenum single crystal MR-10 showing (100) [001] texture. X-ray beam 13° from the pole of rolling plane, rolling direction vertical. Intense spot (top center) from (200) planes normal to rolling direction. $\theta_{200} = 13.1^\circ$, the Bragg angle for $\text{MoK}\alpha$ radiation.

parallel to the cube direction, a cube texture resulted just as in the other straight-rolled specimens, MR-3, MR-7, MR-8, etc., except for a smaller amount of spread.

MR-14, MR-15, and MR-16 were compression-rolled. The fiber texture was found to be mainly [001] parallel to this axis of compression. This is consistent with Barrett's result on compression of iron single crystals with their initial orientations within 22° of a cube axis.⁶

The general features of the recrystallization texture in rolled iron and steel are: 1—rolling plane (100), rolling direction 15° from [$\bar{1}1\bar{2}$]; 2—rolling plane (111), rolling direction [$\bar{1}1\bar{2}$]; and 3—rolling plane (112), rolling direction 15° from [110].⁸ In the case of molybdenum, the recrystallization texture has been reported as the same as the rolling texture but with less spread.⁹ In the present case, the recrystallization texture apparently depends upon the deformation texture: both (001) [100] and (111) [$\bar{1}1\bar{2}$] textures remain unchanged upon recrystallization, but the (001) [011] texture undergoes a rotation of approximately 20° about the normal direction. Whether or not these differences in recrystallization textures can be explained on the basis of the acquisition of energy during the rolling process¹⁰ as a function of the initial orientation should await

further carefully controlled experiments, i.e., a large variation of the initial orientations of single crystals along with a quantitative determination of the resulting textures before and after recrystallization.

Conclusions

1—Those crystals whose initial orientations were remote from a "cube" position developed (001) [110] and (111) [$\bar{1}1\bar{2}$] textures.

2—Those crystals whose initial orientations were close to a "cube" position developed "cube" textures, (001) [100], with a spread about the normal direction.

3—Compression rolling molybdenum single crystals with initial orientation close to the "cube" position gave, generally, a [001] fiber texture.

4—The textures resulting from recrystallization at 1350°C were as follows: the deformation textures, (001) [100] and (111) [$\bar{1}1\bar{2}$], were retained; the

Fig. 9—(110) pole figure for recrystallized molybdenum single crystal after rolling. Ideal orientations indicated as follows: A, (001) [110]; F, (111) [$\bar{1}1\bar{2}$].

deformation textures, (001) [110], underwent a rotation of approximately 20° about the pole of the rolling plane.

Technical Note

Allotropy in the Phase ZrCr₂

by W. Rostoker

IN the course of the development of the phase equilibrium diagram for the system Zr-Cr,¹ the structure of an as-cast alloy having the composition ZrCr₂ was analyzed and established to be isomorphous with MgZn₂ (C14, hexagonal lattice, 12 atoms per unit cell). In a recent paper on the same system, Hayes, Roberson, and Davies² report for the ZrCr₂ phase an isomorphy with MgCu₂ (C15, cubic lattice, 24 atoms per unit cell). It appeared that this conflict might be resolved by assuming a high and low temperature modification for ZrCr₂. That this was the case with the phase TiCr₂ has recently been demonstrated by Levinger.³ Specimens of ZrCr₂ annealed at 1200°, 1100°, 994°, 900°, 834°, 800°, and 700°C, respectively, and subsequently quenched were

Table I. Structure of ZrCr₂ at Various Temperatures

900	MgZn ₂
834	MgZn ₂
800	MgZn ₂
700	MgZn ₂

examined by X-ray diffraction analysis. It was successfully demonstrated that a transition from the MgZn₂ structure at lower temperatures to the MgCu₂ structure did occur at some temperature between 900° and 994°C. Table I lists the observed structures at the various annealing temperatures. In Table II, a summary of line spacings and intensities is given for each of the allotropic modifications. The first six lines of the MgCu₂ structures have been located in the table to illustrate the close similarity between the patterns. Lattice parameters of the two modifications were calculated by a least squares solution

Grain Boundary Sliding and Migration and Intercrystalline Failure Under Creep Conditions

by Hsing C. Chang and Nicholas J. Grant

Creep of very coarse grained, high purity aluminum was studied at 400° to 1100°F with an initial stress range of 50 to 1200 psi. The process of boundary sliding and migration was studied. The driving force of boundary migration under creep conditions is shown to be a combination of strain energy and surface energy. A theory is presented regarding the role the grain boundaries play under creep conditions. From this theory intercrystalline failure of commercial alloys can be explained. Also from this theory an optimum grain size should exist for good high temperature properties of high purity materials.

IN the investigation of the creep of very coarse grained, high purity aluminum previously reported,¹ the cyclic nature of the process of grain boundary sliding and migration has been established by microscopic observation of the actual creep process as well as metallographically. It was also substantiated by measuring localized strains across the grain boundaries. In addition, it was shown how extensive subgrain and fold formation may result from boundary sliding and how the slid grain boundary may become sharply wavy as a result of subgrain formation.

Since the publication of those results, additional information on the process of grain boundary sliding and migration has been obtained. It is the purpose of this paper to report on the direction and driving force of boundary sliding and migration, the effect of grain size, and the effect of temperature. Finally the effect of decreasing purity (alloys 2S and 3S) on the process of boundary sliding and migration is noted. From these results, an explanation is presented for the intercrystalline failure of alloys under creep conditions. The effects of grain size on the creep properties of impure and high purity materials are discussed in the same light.

The experimental procedures and technique have been presented elsewhere.¹ It is only necessary to

state how the 2S and 3S aluminum specimens are prepared.

Machined specimens were first annealed at 600°F for about 12 hr. In order to produce a large grain size the specimens were then stretched 3 to 8 pct. The specimens were marked with reference marks, electropolished, annealed at 900°F for 24 hr and at 1150°F for 12 hr, and repolished.

The grain size of 2S aluminum produced by this treatment is comparable to that of high purity aluminum in the direction of its width of the specimen, i.e., there are 2 to 4 grains across the width of the specimen. However, the grains of 2S aluminum are 3 to 10 times longer in the direction of the specimen axis. On the other hand, the grain size of coarse grained 3S aluminum ranges from 10 to 20 grains across the width of the specimen due to the treatment just outlined and therefore is much smaller than that of both high purity and 2S aluminum. As in 2S aluminum, the grains are about 3 to 10 times longer in the direction of the specimen axis than in the direction of the width of the specimen. The arrangements of the grains in 2S and 3S aluminum were generally irregular; therefore it was difficult to follow the course of the grain boundaries.

Results

Method of Presentation: In order to show the arrangement of the grains, especially the direction and positions of the grain boundaries, traces of the grain boundaries on the four surfaces of the specimens were unfolded and mapped out after macroetching. Figs. 1 and 2 show the structural development drawings of specimens P-3 and P-8 respectively. The two flat surfaces (of which the front one faces the microscope) and the round-edged surfaces will be called the "front surface" and "back surface" and

the "right free edge" and "left free edge" respectively. Capital letters were used to distinguish individual grains.

The results presented below and the observations made came from eight high purity aluminum, five 2S aluminum, and one 3S aluminum specimens. High purity aluminum specimens were subjected to creep at 400°, 700°, and 1100°F with an initial stress range of 50 to 1200 psi. The 2S aluminum specimens were subjected to creep at 700°, 900°, and 1100°F with a stress range of 200 to 800 psi. One 3S aluminum specimen was subjected to creep at 1100°F with a stress of 300 psi. Several hundred micrographs were taken both during the actual creep tests and after the specimens had been removed from the creep furnace. Many micrographs showing the same phenomena were obtained; however, only the most representative ones are presented here.

Most of the micrographs were taken with oblique light so that maximum details could be shown in the same one. All the micrographs will be so presented in the text that the direction of the applied tension runs from top to bottom of the illustration. Specimen numbers are included after the figure number. The grain letter is indicated on the micrographs and schematic drawings in accordance with the structural development drawings of the specimens.

Direction of Boundary Sliding and Migration: The direction of grain boundary sliding was checked frequently by observing the direction of the granular offset on the specimen surface and along the slid grain boundary surfaces. As a result of many observations of this sort, it can be concluded that the direction of grain boundary sliding is governed by the direction of the shearing stress acting on the boundary surface.

In specimen P-3 (Fig. 1, tested at 700°F) a grain G, bounded by a free edge of the test specimen, passes through the whole thickness of the specimen. This grain slid as a whole in the direction of the thickness of the specimen. As a result of this, the back surface of this grain was depressed and the front surface extruded, as illustrated in Fig. 3. This could be readily observed visually. The direction of

boundary migration is indicated by arrows in Figs. 4a and 5a which are micrographs of the front and back surfaces of grain G, respectively. According to the geometry of this grain, it is natural that it should slide in the way observed in Figs. 4 and 5. After examining many cases of this kind it is necessary to point out that the direction of boundary migration is generally toward the side which is depressed, as shown by the solid arrows of Fig. 3; i.e., away from grain G in Fig. 4 and toward grain G in Fig. 5. This position is also the one which has the least boundary surface area.

That the rate of grain boundary migration is severely nonuniform can be seen clearly in Fig. 6 (specimen P-8 tested at 700°F). A schematic drawing of Fig. 6 is shown in Fig. 7 to illustrate the sequence of steps in the migration of this boundary as observed during the actual test. It should be noted that the migrating boundary tends to approach a position which is perpendicular to the specimen axis. This position of the grain boundary is also the one which has the smallest grain boundary area.

Fig. 8 shows a grain boundary of grains A and B of specimen P-3. From Fig. 1 it can be seen that grain B did not go all the way through the thickness of the specimen. The original doubly curved boundary tended to straighten out. It appears that the inflection point of this migrating boundary divides

Fig. 3—Schematic drawing of the direction of boundary sliding and migration in specimen P-3, grain G. Broken arrow indicates the direction of boundary sliding. Solid arrow indicates the direction of boundary migration. Dotted lines indicate a more stable position of the migrated grain boundaries.

this boundary into two regions in which it migrated in opposite directions, as shown by the arrows in Fig. 8.

The three examples cited above signify a type of grain boundary migration in which the grain boundary tends to reduce its surface energy by reducing its surface area. It must be remembered that all the grain boundaries were stabilized after the annealing treatment (without load) of 24 hr at 900°F and 12 hr at 1150°F. The stability was checked by the fact that no boundary migration was observed even by annealing for another three days at 1150°F. Accordingly, the extensive boundary migration must be attributable only to the applied stress. Boundary sliding caused by the applied stress overcomes the locking effect at the stable triple points. This permits the grain boundary surface energy to come into effect, causing the grain boundary to migrate.

Fig. 9a and b (specimen P-8, Fig. 2, tested at 700°F) shows an interesting case in which the migration of the boundary between grains D and E typifies a case in which the strain energy plays the dominant role. Grain E was apparently under com-

pression since sliding had taken place along the boundaries of grains C and E, and grains E and R. Furthermore, because of the blocking effect of the triple points of grains C, D, and E, and of grains D, E, and R, on the sliding of the boundaries of grains C and D and grains D and R, the grain boundary between grains D and E is subjected to bending. The compression side of the bending is in grain E and the tension side is in grain D. It is probably due to this stress system and the locking effect of the two triple points that the upper part of the boundary of grains D and E bulges into grain E during progressive boundary migration. Again note how the grain boundaries between grains C and E

Fig. 7—Schematic drawing of Fig. 6 shows the uneven steps of boundary migration. The numbers indicate the consecutive steps of the grain boundary migration.

and also E and R have migrated into positions approaching 90° to the stress axis, making grain E bounded by rectangular boundaries.

Effect of Grain Size: It has been shown that the process of boundary sliding and migration is a highly cooperative one. It will be expected that the more the grains go across the width of the specimen, the more extensive will be the boundary migration. The reason for this is that whenever one grain boundary slides, the two triple points at the ends of this slid boundary, and therefore the other two grain boundaries constituting the triple point, must migrate in order to maintain the triple point.

Fig. 10 is a fine example showing the large extent

of boundary migration when four grains go across the width of the specimen (in most cases only two grains go across the width of the specimen). I and F indicate the initial and final positions of the grain boundaries. It should be pointed out that specimen P-1, from which Fig. 10 was obtained, was subjected to creep for 234 hr at 700°F (specimen P-8, for 81 hr at 700°F) and therefore more time was allowed for this extensive boundary migration to take place.

The observation that the path of movement of the triple point is zigzag may be explained as below. Fig. 11a to d (all the boundary surfaces are assumed to be perpendicular to the plane of the paper) shows the stages of the movement of a triple point by the process of boundary sliding and migration. It is considered that the boundary of grains A and B slides first. As a result of this sliding an offset or new surface, as indicated by the dashed line 1-2 in Fig. 11a, is produced between grains A and C. This provides the driving force for the boundary of grains B and C to migrate to form a new triple point, 2, as shown in Fig. 11b. If the other two grain boundaries cannot slide, the traces of the triple point movement would be on the extension of the slid boundary. But this is an unlikely situation because the equilibrium arrangement of grains requires the condition that at least two of the three grain boundaries can slide. If now the boundary of grains A and C slides (Fig. 11c), the boundary of grains A and B must migrate in order to form another triple point 3, as shown in Fig. 11d. Therefore, the traces of triple point movement frequently follow a zigzag path.

Fig. 12a shows an interesting case of how a small surface grain was consumed by three large neighboring grains. This is evident by a study of Fig. 12b, which shows the specimen repolished and etched. The etch pits clearly show the old and new grain change. It can be seen from Fig. 1 that, after the

Fig. 11—The stages of the movement of a triple point. A. An offset (1) (2) was produced by sliding along the boundary between grains A and B. B. The boundary between grains B and C migrated from position (1) to position (2) as indicated by the dotted line. C. Offset (2) (3) was produced by sliding along the boundary between grains A and C. D. The boundary between grains A and B migrated from position (2) to position (3) as indicated by the heavy solid line. The heavy solid lines indicate the final arrangement of the grain boundaries.

Fig. 13—Specimen P-9. One hour after reaching 1100°F. Two triple points met in the center of the field and then separated in the top-bottom direction. X60. Area reduced approximately 60 pct for reproduction.

Fig. 14—Specimen P-9. Same field as Fig. 13. One hour and 35 minutes after reaching 1100°F. The grain boundary joining the two original triple points rotated 90°. X60. Area reduced approximately 60 pct for reproduction.

disappearance of the small grain, the grain boundaries of the three large grains went through the thickness of the specimen.

Effect of Temperature: As the temperature increases the atomic mobility (diffusion) increases, and so does the rate of boundary migration. Figs. 13 and 14 were taken from the same field during the creep process of specimen P-9, which was subjected to creep at 1100°F under a stress of about 65 psi. The rate of boundary migration was of the order of 1×10^{-5} cm per sec at the beginning of the test. It is interesting to note how the boundary bounded by the two triple points rotated 90° (from Fig. 13 to Fig. 14).

Fig. 15 is a schematic drawing showing the steps of this rotation process, solid arrows indicating the direction of migration of the triple points. The two triple points must come close to each other, or even meet at point O, before they migrate in opposite directions.

Figs. 16 through 19 show a similar case for specimen P-10, which was subjected to creep at 1100°F under an initial stress of about 50 psi. Each figure represents a successive time interval during the test, namely, 0.5, 3.25, 9.1, and 18.5 hr after reaching the testing temperature, 1100°F.

The specimen fractured after 30.4 hr. The initial positions of the grain boundaries were established before the test by macroetching and are also indicated by the letter I in Fig. 16 (the following dis-

cussion refers to Fig. 16). The triple point marked (1) migrated through a zigzag path in a stepwise manner toward the lower left direction, while the triple point marked (2) migrated toward the upper left direction also in a stepwise manner, as indicated by the solid arrows. They come very close to each other at point A. After point A, the appear-

Fig. 16—Specimen P-10. One-half hour after reaching 1100°F. Note the initial grain boundary connecting two triple points, 1 and 2, rotated about 90°; now lying about 68° to the specimen axis. Solid arrows indicate the directions of the migration of the two triple points, 1 and 2, after which they met in the neighborhood of point 3. Dotted arrows indicate the directions of separation of the newly formed triple points to position 4 and 5. X60. Area reduced approximately 60 pct for reproduction.

ance of the traces of the grain boundaries indicated that the two triple points must have separated very rapidly, one to the upper left, marked (4), and the other to the lower right, marked (5), as indicated by the dotted arrows. It has been suggested by Fullman, Burke, and Turnbull² that the two migrating triple points may meet at a common point during grain growth before they separate in a direction different from that which they came to meet. This common point is marked (3). This is a plausible suggestion based on the more exact picture shown in Fig. 13. Once the two triple points occupy a common position, a maximum instability must exist from a grain boundary configuration viewpoint.³ Due to the magnitude of this instability, the two new triple points migrated at a very rapid rate to new positions (4) and (5), indicated by the dotted arrows, leaving no traces of grain boundaries as is usual in a slower process of migration.

The left triple point (4) disappeared at the left free edge of the specimen half an hour after reaching the creep testing temperature at 1100°F, while the right triple point marked (5) continued to migrate toward the right free edge of the specimen to a position (6) in Fig. 17, taken 3.25 hr after reaching 1100°F. The grain boundary connecting the two new triple points now becomes one bounded by one triple point (6), Fig. 17, and the left free edge of the specimen, and is the boundary between grains A and D. This boundary between A and D had migrated in steps, as shown by the arrow in Fig. 17, in approaching a position almost perpendicular to the axis of the specimen. Evidence of sliding of the boundary between grains A and D during consecutive steps of migration can be obtained by observing the offset of the traces of the old grain boundaries (Fig. 16). Fig. 18, taken 9.1 hr after reaching 1100°F, indicates that the boundary between grains A and D swung to a position still closer to 90° to the axis of the specimen, and the new triple point (6), Fig. 17, of grains A, E, and D moved closer to the right free edge of the specimen, as shown by (7) in Fig. 18. At the end of the test (30.4 hr after reaching 1100°F), the grain boundary between grains A and D had migrated to a position almost perpendicular to the axis of the specimen, while the new triple point of grains A, E, and D almost disappeared at the right free edge of the specimen, Fig. 19.

All the results presented above came from high purity aluminum specimens which were subjected to creep at 700° and 1100°F. At 700°F the grain boundaries show very extensive grain boundary sliding and migration before the grains show signs of deformation, and this is even more apparent at 1100°F. However, no appreciable boundary migra-

Fig. 17—Specimen P-10. Same field as Fig. 16, 3.25 hours after reaching 1100°F. The triple point 4 disappeared at the left edge of the specimen. The triple point 5 migrated to position 6. The new grain boundary between grains A and D tended to rotate perpendicular to the specimen axis as indicated by the solid arrow. The evidence of sliding of the boundary between grains A and D can be obtained by observing the offset, indicated by a. X60. Area reduced approximately 60 pct for reproduction.

tion was found for specimens which were subjected to creep at 400°F for up to 475 hr, whereas the usual evidence of grain boundary sliding was still observed.

Effect of Impurities: Boundary sliding and migration were observed in 2S aluminum for creep testing temperatures of 900° and 1100°F. This is shown in Fig. 20a and b at 900°F. The extent of grain boundary migration was observed to be a little greater at 1100°F than at 900°F for 2S aluminum. However, the extent of boundary migration for 2S aluminum was very much smaller at 900°F than in the case of high purity aluminum at 700°F (compare Fig. 20a with Fig. 10). It has been observed in high purity aluminum that the grain boundary usually tended to reduce its surface area during migration. It may be seen from Fig. 20 that 2S aluminum behaves in a similar manner but with materially less grain boundary migration. The course of grain boundary migration is more irregular than has been presented above for high purity aluminum. A 3S aluminum specimen subjected to creep at 1100°F for 79.5 hr showed almost no evidence of boundary migration although the usual signs of fairly restricted boundary sliding were observed. Based on these observations, it was quite evident that the alloy and impurity content of 2S aluminum fixes the grain boundary more rigidly, allowing only a small amount of migration, whereas in 3S aluminum migration is restricted almost to the vanishing point. The effect of such grain boundary fixation results in the low ductility noted by Servi and Grant⁷ as the alloy content of aluminum increases from high purity to 2S and then 3S aluminum.

Discussion

Intercrystalline Failure: It has been shown metallographically that grain boundary migration is very structure-sensitive. Boundary migration may be

Fig. 18—Specimen P-10. Same field as Figs. 16 and 17. 9.1 hours after reaching 1100°F. The triple point 5 in Figs. 16 and 17 continued to migrate toward the right edge of the specimen. The new boundary continued to rotate perpendicular to the specimen axis as indicated by the solid arrow. X60. Area reduced approximately 60 pct for reproduction.

severely restrained by a second phase as in the case of 2S aluminum, or it may be almost completely stopped with larger amounts of second phase as in the case of 3S aluminum, as predicted by Zener³ on the basis of surface energy considerations. It has also been shown that boundary migration is a kind of recovery process which makes further boundary sliding possible.¹ In impure or alloyed materials, grain boundary migration becomes less significant, and sliding is restricted to a fixed boundary. Since the grains are strengthened by alloying or a second phase, the stresses which are built up around the triple point as a result of boundary sliding cannot be released as readily, if at all, by deformation in the grains. This stress built up by sliding along the same boundary would eventually give rise to cracks at or in the vicinity of the slid boundary. Stress concentration caused by cracks would result in intercrystalline fracture. This is why commercial alloys subjected to high temperature creep show intercrystalline fracture, whereas no sign of intercrystalline failure has been observed for high purity aluminum in the present investigation. In the case of high purity aluminum, boundary sliding not only occurs extensively because of the progressive boundary migration but also causes extensive subgrain and fold formation as shown in ref. 1. Such grain

boundary mobility prevents intercrystalline fracture.

Furthermore, in impure or alloyed materials, the boundaries would be expected to be more irregular and are shown metallographically to be so (see Fig. 20). During boundary sliding an irregular or wavy grain boundary would give rise to local high stress regions not only at the triple point but also at odd positions where the grain boundary is not plane. Therefore, cracks may develop not only at the triple point but also along the slid grain boundary.

Effect of Grain Size on Creep Properties: High Purity Metals: It is interesting to explore the ques-

Fig. 19—Specimen P-10. Same field as Fig. 16. 18.5 hours after reaching 1100°F. The triple point 5 in Fig. 16 migrated to point 8. The migration of the new grain boundary indicated by the arrow almost stopped after reaching a position nearly perpendicular to the specimen axis. X60. Area reduced approximately 60 pct for reproduction.

tion of the effects of grain size on the creep properties of a metal on the basis of the observations of the behavior of grain boundaries in this work and in a previous publication.¹ It is stated conventionally that above the equicohesive temperature or transition temperature (the temperature at which the material changes from low temperature behavior to high temperature behavior) the larger the grain size the better the creep properties as measured by minimum creep rate and rupture life. This statement, while generally true, has certain limitations and exceptions. High purity metals do not follow this rule over the entire range of grain sizes,^{4,5} and it is possible that some single-phase alloys may also not conform entirely.⁶ By varying the grain size ten thousand fold for high purity aluminum

Fig. 20a—Specimen 2S-7. Grain boundary migration in 2S aluminum at 900°F. I and F indicate the initial and final positions of the migrating grain boundary respectively. X150. Area reduced approximately 60 pct for reproduction.

(99.995 pct), Crussard⁴ was able to find an optimum grain size at which the secondary creep rate is a minimum. This conclusion is also proved to be true for zinc specimens.

As shown previously,¹ boundary sliding will inevitably cause deformation in the grains either in the form of subgrains or in the form of folds, or if the grain size is large enough, by slip when sufficient deformation has occurred.⁷ In other words, the ability of the grains to accommodate deformation created by boundary sliding must be taken into account in order to evaluate the resistance to creep for a high purity metal. It should also be remembered that the difference in composition and in strength of the grain and grain boundary in very pure metals is quite small.⁷

For high purity material of a grain size smaller than the optimum, the resistance to creep is small because boundary sliding has many loci, and once such sliding has occurred along boundaries favorably oriented, the grain boundary deformation can be transmitted to other boundaries. The deformation can take place in this manner with less deformation in the grains. In order to deform the specimen as a whole it is not necessary for the deformation to go completely through the grain. For example, folds, one of the noted mechanisms of deformation¹ (see Fig. 9, grain E), cannot develop completely through a grain because of the blocking effects of the grain boundaries. As will be shown in a later paper, the development of folds depends primarily on the length of the sliding grain boundary relative to the length of the grain in the direction of the sliding boundary. In other words, fold deformation depends on the grain size.

For high purity metal of a grain size larger than the optimum, the deformation initiated by boundary sliding can be transmitted to and accommodated by deformation in the grains because the grain deformation is now progressively less influenced by grain boundaries as the grain size increases. Thus while the grain boundary may deform before the grain at elevated temperatures, the grain boundary nevertheless has some blocking effect upon the deformation taking place in the grain. Thus for high purity metals, the resistance to creep is also small for very large grain size materials.

Alloyed or Impure Metals: While it is difficult to predict the effects of grain size on the creep or creep-rupture properties of commercial materials, it can definitely be stated that the effects of grain size are not necessarily the same for both classes of metals. The existence of an optimum grain size, prior to reaching the extreme grain size where orientation effects of the grains become controlling, has not been demonstrated. From fairly limited data on 2S and 3S aluminum it appears that the grains are relatively strengthened more than the grain boundaries. Barring grain boundary precipitates this is probably true of other metals. In 2S and 3S aluminum while it is possible to eliminate slip in the grains for a given grain size, it has not been possible to eliminate grain boundary sliding. If the above is true, then high temperature strength depends on the amount of strain which the grain boundaries can sustain before cracks develop, and on how easily or readily the cracks are propagated. Examination of many hundreds of micrographic structures has clearly demonstrated that the grain boundaries which slide most readily and most extensively are those which are at 45° to the stress

axis and offer a smooth plane boundary. It is readily evident that the fine grained commercial alloys offer many grain boundaries which satisfy the above conditions (see Figs. 22 and 23 of ref. 7). In coarse grained commercial alloys, on the other hand, the grain boundaries are usually curved, are irregular (not plane), and offer only very short sections where the grain boundary can slide readily or extensively (see Fig. 20). But even in these sections the grain, being considerably stronger than the grain boundary, acts to restrain deformation and cracking.

Summary and Conclusions

From creep studies of very coarse grained, high purity 2S and 3S aluminum at 400°, 700°, 900°, and 1100°F, the following conclusions regarding the process of boundary sliding and migration can be drawn.

1—The direction of boundary sliding is primarily governed by the direction of the shearing stress acting on the boundary surface. The driving force which controls the direction of boundary migration is shown to be a combination of strain energy and surface energy. The latter is important at high temperatures.

2—The zigzag nature of the movement of the grain boundary triple point is considered to be a necessary consequence of the highly cooperative process of grain boundary sliding and migration because the direction of boundary migration depends primarily on the direction in which the grain boundary slides as the initial step. The extensiveness of boundary migration during creep of high purity aluminum at high temperatures, particularly of fine grain size, is believed also to be due to the highly cooperative nature of grain boundary sliding and migration.

3—Boundary migration and sliding were observed in 2S aluminum at 900° and 1100°F. As a result of the alloy and excess phase content, the amount of boundary migration was much smaller and its course more irregular than was observed in high purity aluminum. For 3S aluminum at 1100°F, normal boundary sliding was observed (leading to intercrystalline fracture) without any clear evidence of grain boundary migration.

4—A theoretical picture is proposed to explain the superiority of coarse grained structures in commercial alloys.

Determination of the Absolute Grain Boundary Energy of Gold at 1300°K

by F. H. Buttner, H. Udin, and J. Wulff

GRAIN boundaries, the interface between adjacent crystals differing only in respective orientation, have been the object of much experimental and moderate theoretical attention for many years. The earlier experimental work was primarily concerned with the effect that grain boundaries have on the physical behavior of metals, while the basic nature of the boundaries themselves drew only secondary attention. A complete turnabout has been witnessed in more recent years, however, as researchers are now undertaking investigations bearing as directly as possible on the character and physical properties of the grain boundary. Quite comprehensive reviews of the past literature on the subject of grain boundaries have been reported on numerous occasions by various authors, and together these references represent a thorough coverage.¹⁻⁷

It becomes evident in these reviews and other papers⁸⁻¹⁵ that the properties of grain boundaries can be explained by regarding a grain boundary as a crystalline region of transition between two unmatched grains. Studies show that grain boundaries have a definite interfacial energy. By measuring the geometry about a point where three interfaces meet in equilibrium, the energy of any two boundaries can be measured with respect to the third. If the absolute interfacial energy of one boundary is known, the absolute energy of the other two boundaries can be calculated. This apparently holds true for any system of phases and interfaces.¹⁶⁻²⁵

Most studies have been carried out on solid-solid or liquid-solid systems, or systems of both. However, if about the point of intersection one phase is vapor and the other two are disoriented grains, then two interfaces are surfaces, and one is a grain boundary. Investigations leading to relative grain boundary energy for this particular system have been made by Fullman,²³ Greenough and King,²⁴ and Bailey and Watkins.²⁵ Herring²⁶ treats the system mathematically and arrives at an equation, which appears as Eq. 1, in a form consistent with the reference angles indicated in Fig. 1,

Fig. 1—The interfacial stress pattern about a point in the root of the thermally etched grain boundary groove.

$$\gamma_B = \gamma_1 \sin \alpha + \cos \alpha \left(\frac{d\gamma_1}{d\alpha} \right) + \gamma_2 \sin \beta + \cos \beta \left(\frac{d\gamma_2}{d\beta} \right) \quad [1]$$

As the system of interfaces comes to equilibrium, a groove of angle θ appears at the intersection of the grain boundary with the surface, an effect first observed by Rosenhain and Humfrey.²⁷ Eq. 1 is essentially a summation of the vertical components in Fig. 1 set equal to zero, where γ_1 and γ_2 are surface tension vectors lying along the side of the groove at point O in the groove root. The differential vectors represent the forces tending to rotate the surface into a position that will expose a crystal cleavage surface of lowest energy.

Chalmers, King, and Shuttleworth²⁸ simplify Eq. 1 by assuming the differential vectors equal to zero, $\gamma_1 = \gamma_2 = \gamma_{\text{surface}}$, and arrive at the following equation:

$$\gamma_B = 2\gamma_s \cos \frac{\theta}{2} \quad [2]$$

Greenough and King²⁴ use Eq. 2 for determining the grain boundary energy of silver using prepared bicrystals of known orientation. Bailey and Watkins²⁵ have done the same for copper, as did Chalmers and others on lead. These authors report the grain boundary values as ratios relative to the surface energy.

In the above work, the orientation of grains forming the grain boundary in all cases was controlled so

Fig. 2—Perspective of exaggerated grain boundary groove, showing the point O, the force pattern, the angle ϕ , and other important features and dimensions.

as to get disregistry by relative rotation about an axis parallel to the plane of the grain boundary under consideration. This creates "tilt" boundaries consisting of edge dislocations of various concentrations over the surface proportional to the amount of rotation. The generalized results show that the grain boundary energy increases sharply with increasing rotation up to a neighborhood of 15° to 25° , in which region the energy slope tapers off to zero at a saturation level of roughly one third the average surface energy. At still higher angles of rotation where the grains approach a twin orientation, the energy falls off in the same manner. In passing through the twin orientation, the energy falls and rises to form an energy cusp.

The various methods used to measure the groove angle have been critically reviewed by Brooks.⁷ These consist of various techniques of cutting through the groove and observing the root angle on the surface of the cut. Greenough and King²⁴ introduced a goniometric reflected light method, which although imperfect, appears promising from the standpoint of quick and easy measurements of good precision. Essentially, this method is used in the present work.

As was pointed out above, previous investigators studied specially prepared tilt boundaries containing edge-type dislocations. In this paper, boundaries are studied as they appear on 5 mil gold wires recrystallized into a bamboo structure. These boundaries are more or less randomly oriented, since no controlled recrystallization process is involved, except for possible preferential grain orientations arising from the original texture of the cold-drawn

gold wire. The nature of a grain boundary formed at random may be described as a superimposed tilt and twist boundary containing a blend of edge and screw dislocations.²⁰ The purpose of this paper is to outline and discuss the results of a study of random boundaries.

Experiment and Results

In the course of surface tension experiments on copper,³⁰ silver,³¹ and gold,³² conditions of thermal and phase equilibrium were maintained about fine wires held at high temperatures for long periods of time. Grain boundary grooves appear on the surface of these wires during the experimental run and reveal the bamboo structure of the wires. The angular dimensions of these grooves can be used to measure the energy of the grain boundaries. Details of the equipment applied and the procedures followed in the treatment of these fine wires are outlined in detail in the above reports on the surface tension experiments on copper, silver, and gold.

A three dimensional sketch of a wire section showing an exaggerated groove is shown in Fig. 2. The idealized grain boundary running perpendicular to the wire axis produces a groove girding the wire at the surface intersection of the grain boundary. At some angle of rotation, ϕ , from the arbitrary axis, a point O, is observed through a metallurgical microscope. The plane passing through the element of the wire and the wire axis in Fig. 2 is the plane of the paper in Fig. 1. As ϕ changes with rotation of the wire, point O moves along the groove. One of the objects of the experimental procedure is to measure the angles of the force pattern at points along the root of the groove as ϕ rotation passes through 360° . The method used to measure the groove angles employs the goniometric principle introduced by Greenough and King.²⁴

Figs. 3 and 4 show the goniometer apparatus used to measure the important angles. The equipment is in two parts, the goniometer in which a wire is mounted, Fig. 3, and a metallurgical microscope through which light reflections from the wire are observed, Fig. 4. In the goniometer, the wire is strung between two gear linked heads such that the wire axis is perpendicular to the optical axis of the microscope. The gear linked heads are set in bearings in a mounting block. The mounting block has three mutually perpendicular translational degrees

Fig. 3—The goniometer showing wire mount and gear linked head.

Fig. 4—The goniometer in position beneath the metallurgical microscope.

Fig. 5—The geometry about point O showing the principle of angle measurement. (a) Measurement of α and β . (b) Check measurement.

of freedom; up and down in the optical axis, forward and backward from the operator of the device, and sideways along the swing axis. Such freedom makes it possible to station point O at the intersection of the optical axis and the swing axis, Y, Fig. 2.

In order to be able to measure the groove angle by reflected light, and also be able to view the wire from any side through the microscope, three degrees of rotational freedom have been built into the apparatus in the manner of a goniometer. First, the wire can be rotated about the X-axis through ϕ degrees; second, about the optical or Z-axis for measuring the perpendicularity of the boundary trace with the wire axis; and third, about the swing axis, Y, for observing the reflected beam.

For reasons of clarity in describing the measurement procedure, first assume that the microscope sends forth a parallel beam of light. When the wire is properly aligned as described above, a bright line of reflection is seen along the uppermost element of the cylindrical surface with a break at the position of the groove. Upon rotating the "swing" slightly, the line-element reflection disappears and is replaced by a spot reflection at the top of one side of the groove. The rotation is continued through an angle α while the spot travels down the groove side and disappears at the root. The geometry involved here is shown in Fig. 5a. The measurement is taken from a protractor mounted on the side and a pointer rotating with the swing. Reversing the swing and watching for the point where the spot disappears on the other side of the groove produces the angle β . The groove angle is calculated by difference and can be checked as in Fig. 5b by measuring the angle starting where the spot disappears on one slope to where it disappears on the other. That measured angle is equal to $(180^\circ - \theta)$.

The light beam, however, is not parallel, but has a measured divergence at its source of 18° . Thus for the measurement of α and β , the swing must be rotated 9° beyond the point necessary for the reflected spot to disappear if the beam were parallel. Similarly the measurement of θ is 18° too high. These corrections were made in the reported values.

In Fig. 6 several plots of θ vs ϕ are shown. α and β in these cases are not shown, but vary independently of each other.

It became evident that θ varies in a complicated fashion as a function of at least four vectors, Fig. 1. A simple visualization is not only to see θ opening and closing with ϕ rotation, but simultaneously rocking back and forth in the axial direction with the same rotation due to the independent variation of α and β . However, a good average value for θ can be found for a given grain boundary by taking at least four, and preferably more, readings for θ at equally spaced ϕ intervals around the wire. This was done for 69 grain boundaries. The results are plotted as a spectrum in Fig. 7. The average θ for these is 164.5° . Since the differential vectors vary through positive and negative values, they average out to zero in the average vector pattern, wherein also $\gamma_1 = \gamma_2$. Therefore, Eq. 2 applies in the average case. Using the average surface tension for gold, $\gamma_s = 1400 \pm 65$ dynes per sq cm, from Buttner, Udin, and Wulff,³² the average grain boundary energy turns out to be 365 ± 50 ergs per sq cm.

Discussion and Conclusion

Two features of Fig. 7 are deserving of attention. First, the curve is a typical distribution curve with some scatter about the average θ , and second, it contains a few grain boundaries of comparatively high and a few grain boundaries of comparatively low measured average groove angles. The scatter itself may arise from: 1—the probability combinations within the system, 2—errors in the measuring technique, and 3—the limitations inherent in small wire size. The high average groove angles may result from low energy boundaries, lying in an energy cusp, breaking into a cylindrical surface of average surface tension. The low average groove angles may be a result of: 1—the possibility of an average grain boundary breaking into a cylindrical surface of excessively low average surface tension, 2—the likelihood of the differential vectors being negative in direction, or 3—the outside possibility of inverted energy cusps.

The angle θ depends on four surface sensitive vectors, and one grain boundary vector, the magni-

Fig. 6—Several typical plots of groove angle (θ) versus circumferential position of point O in the groove (ϕ).

Fig. 7—Spectrum of average grain boundary θ versus number of grain boundaries having that average value.

tude of which, for a given groove, depends on the unique orientation of the two grains concerned. In other words, two grains may expose a high or low average energy surface at the groove wall, while at the same time forming a maximum or sub-maximum grain boundary energy, depending on the relative orientation of the two grains on either side of the boundary. The size of the average groove angle can, therefore, cover a spread of values, resulting from the combinations and permutations of the above possibilities. The number of different recognizable combinations and permutations depends on the resolution of the measuring instrument, or its ability to distinguish between small differences. An example is the above-mentioned combination of a maximum interfacial tension with a low average surface tension, which can lead to shallow grooves or an excessively high θ . This sort of thing can occur to various lesser degrees and lead to a sizable scatter about a mean, as seen in Fig. 7. This is what is meant by probability combinations within the system.

Some error exists in the reflected light method. Since the edge of the light beam is not sharp, a human uncertainty occurs in deciding when, during the swing rotation, the spot disappears. This difficulty did not seem as pronounced as Greenough found it in his measurements. Perhaps a dimly reflecting line is more confusing than an equally dimly lit spot. Precision of repeated measurements fall to within a half of a degree. In deep angle grooves, the ridge that builds up at the brink of the groove can sometimes reflect a spot from its outer side and appear to blend with the spot reflected from the opposite groove wall. This may lead to high values for α and β , and must be carefully watched. It is easily recognized when half the spot disappears at once and the other half remains during a further swing. The check against human error described in the procedure goes far in increasing the precision of measurements.

Although the finer the wire size the simpler it is to get a bamboo structure, there would be a distinct advantage in using the largest diameter wire possible. Point O in Figs. 1 and 2 under the microscope actually appears as the cross-sectional area of the microscope light beam. The beam covers a section of the circumference equal to the diameter of the beam and may be measured in terms of the central angle in terms of ϕ . In the case of 5 mil wires, the edges of the visible light spot is reflected from elements of the wire subtending an estimated central angle of 10° . Therefore, if any local contour irregularity exists, the reflection can come from the same element of the groove wall for positions of ϕ separated as much as 10° . Of course, irregularities that could cover a section of circumference of that extent are noticeable and can be avoided. Those cov-

ering smaller increments are difficult to notice and can account for some error in the θ vs ϕ curves.

In Fig. 6, several groove traverses are plotted in 25° intervals of ϕ , and fairly smooth curves can be drawn through the points. However, in the topmost plot where intervals of $\phi = 5^\circ$ were followed, a suggestion of sharp peaks and curved valleys becomes evident in the circumferential contour of the groove walls, a situation shown by Wulff³⁵ to be the most thermodynamically stable. Energy-wise, this indicates the existence of a corresponding series of curved maxima and cusped minima. A detailed discussion of surface contour and its associated energy is well reviewed by Herring and Nichols.³⁶ It is significant to note that the effect is prominent here when the metal is in equilibrium contact with its own saturated vapor. It is also encouraging to find that the reflected light method appears to have sufficient resolving power to pick up these sharp variations. A more detailed study of these hills and valleys would be desirable, but is hampered by the limitations of wire size in this case.

Another contour feature found in these fine wires is the occurrence of flat spots or facets in the circumferential contour of some groove walls. Facets of this sort in metallic crystals in regions of very small dimensions have never been observed to form in this manner before, to the knowledge of the authors; not even under the critical examination of the electron microscope. Tungsten needle points heated in vacuum have been found to round off into a constant radius at the tip. Although this has been a source of wonder in some circles, it has been suggested that the low free-energy contour would appear in systems of small dimensions where solid-vapor equilibrium exists.³⁸

A detailed theoretical discussion of facets is outside the scope of this paper. However, the existence of facets, like contours, enters in here insofar as they have been observed and as they affect the results of this study.

In some grooves the facets are large and noticeable, while in others they are not. Also variations in average amplitude of hills and valleys appear from groove wall to groove wall. It is generally true that groove walls of high amplitude contours are those in which facets are often noticeable. Measurements of groove angles where the groove wall is a facet are apparently not significant and were discarded.¹⁹ On the other hand, small facets may go unnoticed and cause errors in measurements. For example, in some positions of ϕ , an unnoticed facet may be stationed at some angle far enough from perpendicularity with the X-Z plane to throw the reflected beam off sideways, and out of the range of the microscope. In this case the spot would disappear prematurely and introduce an error in angle measurement. Furthermore, at the edge of a facet, the groove surface in the circumferential direction becomes slightly concave where it blends into the normal average convex contour. In this region, the reflected spot may drift to the right or left and reflect from elements other than the element the optical system is set on. Over a small range of ϕ 's in this region, the spot can very easily be disappearing from the same element, which would result in a horizontal section of the θ vs ϕ plot. In going to a larger wire, the facets as well as the light beam would cover a smaller fraction of the circumference, making it possible to make more certain measurements at smaller ϕ intervals. All of these

Fig. 8—Force pattern similar to Fig. 1 where $\theta = 180^\circ$.

improvements together should produce a more detailed curve of higher accuracy and greater reliability.

In comparing the relative merits of Eqs. 1 and 2, it appeared that ignoring the differential vectors of Fig. 1 reduces the accuracy of Eq. 1 to an approximation of Eq. 2. This conclusion is based on the findings of Dunn, Daniels, and Bolton, who did their work on tricrystals. Evidence found in the present work indicates that the same is true for the present system involving a vapor phase. Several instances were observed where a fairly deep groove became shallower and disappeared with ϕ rotation at three equally spaced regions about the wire. In places where $\theta = 180^\circ$, the force picture must have been as shown in Fig. 8. In this case, the sum of the two differential vectors equals the grain boundary energy vector. Although the differential vectors can be zero in some cases, they can at times reach fairly sizable positive and negative values, which makes it dangerous to discount them in all cases.

In conclusion, it appears from evidence presented in this paper, that the fine wire technique as described is a suitable method for obtaining the absolute average grain boundary energy for systems where the absolute average surface energy is known. Although the use of fine wires has its limitations as described above, these difficulties have a way of ironing themselves out when the results are computed as averages from a large number of measurements. The method shows the way for making detailed studies of surface tension wherein absolute surface energy values can be found for known free surfaces. This, of course, would require the use of larger wires and possibly X-ray identification of the exposed surfaces.

Summary

In studying the dimensions of the thermal grooves appearing in fine wires with bamboo structure, it was found that the groove angle is a result of independent hill and valley variations in slope of the groove walls with position around the boundary. A given slope in the wall on either side of the grain boundary depends on the magnitude of surface tension vector lying in that wall, and a differential vector standing perpendicular to that surface.

A statistical study of the average groove angle of many grain boundaries produced an overall average of $\theta = 164.5^\circ$. This value leads to an average grain boundary energy of 365 ± 50 dynes per sq cm for gold at 1300°K .

The present work introduces a method whereby the general grain boundary energy of metals in equilibrium at high temperatures can be found, assuming the average surface energy of the material is known for the same temperature.

Nature of the Creep Curve

by Thomas H. Hazlett and Earl R. Parker

An understanding of the mechanism of creep of metals requires an accurate knowledge of shape of the time-deformation curve. An expression is developed which accurately expresses the creep curve for a number of structurally stable metals and alloys.

VAST strides have been made in the development of high temperature creep resistant alloys; however, no sound understanding of the physical mechanism of creep exists to date. Consequently, creep resistant alloys are still developed by "cut and try" methods formerly so successful but now yielding returns at a continuously diminishing rate. It is apparent to all workers in the field that if the mechanism of creep were understood, much fruitless labor could be avoided. The dearth of fundamental knowledge has not discouraged the theorists. Speculation has flourished and numerous theories of creep have been proposed. A critical review of these theories reveals that, even though there are some general areas of agreement between the majority of the workers, there are many basic questions yet to be resolved.¹

It is generally conceded that theoretical speculation is far in advance of experimental evidence. The shortage of reliable creep data greatly hinders more rapid progress in this field. It is essential that the

effects of different stresses and temperatures on the creep characteristics of metals be quantitatively determined. Once this has been accomplished, it will then be possible to evaluate the effects of alloying additions and, it is hoped, to provide a firm basis of facts for theoretical treatment of the creep phenomenon. The work reported herein was undertaken to determine the effects of such variables as stress, temperature, alloying, and structure on the creep characteristics of some metals.

Material and Equipment

Nickel was selected as the base material for the current investigation and an experimental program was initiated to determine the effects of temperature and stress on the creep characteristics of this material. Since a large quantity of high purity nickel was required for the proposed program and such material was not commercially available, it was decided to refine, cast, and prepare the required metal in our own laboratory. The resulting nickel test bars had the following composition, given in percentage by weight: Fe, 0.030 (1); Si, 0.003 (2); Ca, 0.001 (1); Mg, 0.020 (2); and S, 0.002 (2); to make total impurities of 0.056. The nickel (balance by difference) is 99.944 pct. The details of the purification process are described elsewhere.² This

material was also used as the base metal for preparing the alloys mentioned later.

All tests were performed in single specimen creep units similar to those shown in Fig. 1. All units were completely independent of each other to prevent any possibility of shock loading due to failure of another specimen. Load was applied through a knife-edge lever arm system, but since the ultimate

Fig. 7—Nonlinear logarithmic creep curves for lead and aluminum.

goal of the study was to provide data which would be of value for theoretical studies, all tests were performed under conditions of essentially constant stress rather than constant load. The stress variation was held to less than $\frac{1}{2}$ pct by means of modified lever arm system,⁸ which consists of an auxiliary arm attached to the back end of the lever and projecting downward from it at an angle of 90° . The lever systems were counterbalanced and calibrated for several load ranges to correct for possible bending of the lever.

Fig. 8—Creep curves for high purity nickel on rectangular coordinates.

The specimens were heated by tube-type, wire-wound resistance furnaces with three independent windings. The end windings were individually controlled with small auxiliary controllers and the temperature of the center winding was determined and controlled by a thermocouple placed at the center of the specimen. High sensitivity millivolt controllers with an expanded range were used for this purpose. Temperature distribution along the specimens was held constant within $\frac{1}{2}^\circ\text{C}$ and the temperatures of the center of the specimens did not vary more than 1°C during the test.

The specimens were machined with two reduced sections in tandem; one having a reduced length of 1 in. and the other 3 in. Strain measurements were made by means of extensometers pinned to each of the three shoulders of the specimens. The extensometer assembly was made in three portions which were free to move relative to each other in the direction of the specimen axis. The elongation of each reduced section was measured between shoulders and the differences taken as the elongation in 2 in.

Strains were measured with precision dial gages which have been modified to permit automatic recording of all data.

Data and Analysis

The data originally obtained from this program were plotted in the usual manner on rectangular coordinates and the "secondary" or "steady state" creep rate determined for each as illustrated in Fig. 2. This concept of a steady state creep rate has long been accepted and used both by designers and theorists as a reliable parameter to define the creep behavior of materials under given conditions.

However, as pointed out by Lubahn,⁴ such a concept may be unjustified. When the data of Fig. 2 were replotted on a vastly expanded time scale, as shown in Fig. 3, an apparent constant strain rate is

Fig. 9—Initial part of creep curves of Fig. 8 with expanded coordinates.

Fig. 10—Linearity of low temperature creep curves for high purity nickel when time-dependent strain only is used.

Fig. 11—Linearity of nickel alloy creep curve after first hour of test when total strain, ϵ , is used.

Fig. 12—Logarithmic plots of complete creep curves showing effect of ϵ_0 correction.

again found, but of a magnitude differing from that previously obtained.

Subsequent work by the General Electric Research Group demonstrated that in many cases, creep data obtained from constant stress tests showed a continuous decrease of creep rate up to the point of initiation of failure.⁵ This is illustrated by Fig. 4, which shows that when the logarithm of the strain, ϵ , is plotted against the logarithm of the time, t , the resulting creep curve is linear. Conse-

Fig. 13—Rectangular coordinate plot of creep curve shown in Fig. 12.

quently, the data may be represented by the following empirical relationship:

$$\epsilon = At^b \quad [1]$$

where A and b are constants.

A critical re-examination of all available constant stress creep data substantiated the thesis that the creep rate does continuously decrease as postulated by Fisher and Hollomon.⁵ Consequently, it was concluded that the concept that the creep rate eventually becomes and remains constant is incorrect, and the use of such a parameter for correlating constant stress creep data is unjustified.

Since it is highly desirable, if not essential, to utilize some specific parameters when comparing results of creep tests, Eq. 1 was adopted with considerable success as shown by the creep curves for nickel in Fig. 5. This was further substantiated by Lubahn's data on mild steel,⁵ Carreker's results on platinum,⁶ and by Andrade's constant stress creep curves for copper.⁷ However, as the stress and temperature test range for nickel was expanded, it was found that some data did not conform to this simple relationship, but instead produced curved lines which were concave upward on the logarithmic plot. The lack of linearity on the logarithmic plot was also

evident in the data obtained by Andrade for lead and that for aluminum obtained by Grant at M.I.T.⁸ These curves are shown in Figs. 6 and 7.

The nickel curve of Fig. 6, which exhibits this behavior, is shown plotted on rectangular coordinates in Fig. 8, together with a curve obtained from a test performed at 700°C. It may be noted that the total creep strain for the lower temperature test appears to consist of two parts; first, an instantaneous strain and second, a time dependent strain. The region of rapidly decreasing creep rate usually associated with the early portions of the creep curve is not pronounced in the 550°C data, but rather large strains do occur at the time the load is applied. This

Fig. 14—Time-dependent strain creep curves for nickel and aluminum.

is more clearly portrayed in the expanded scale plots of the same data shown in Fig. 9. The more typical 700°C curve is again shown for comparison. It can be seen that the 550°C curve may be extrapolated to a finite strain at zero time with reasonable certainty, but for the 700°C curve the strain rate is increasing so rapidly with decreasing time that the strain at zero time is very indefinite.

On the basis of data exemplified by the 550°C curve, it was found that if the instantaneous strain

Fig. 15—Time-dependent strain creep curves for lead and aluminum.

Fig. 16—Effect of additions of titanium in solid solution on creep curves of high purity nickel.

upon loading was subtracted from the total strain, the resulting time-dependent deformation plotted linearly with time on logarithmic coordinates as shown in Fig. 10.

Thus it appears that Eq. 1 should be modified to the form:

$$\epsilon - \epsilon_0 = At^b \quad [2]$$

where: ϵ is the total true strain; ϵ_0 , the instantaneous strain at loading; t , the time; and A and b are constants. However, this does not explain the linearity of the high temperature curves such as the 700°C curves of Fig. 5, since it would appear from Fig. 8 that the zero time intercept of the 700°C curve is of the same order of magnitude as the 550°C curve.

In order to clarify this situation, special high speed strain recording equipment was constructed to determine accurately the initial part of the curve. For times greater than 1 hr, the logarithmic plot of these data yields a straight line as shown in Fig. 11. However, when data at very short times are plotted, the line shows a pronounced curvature as illustrated in the upper curve of Fig. 12. Here it may be seen that the linearity from 1 hr on is merely a very close approximation, the curvature increasing as the time decreases. A value of $\epsilon_0 = 0.0070$ is required to make the total curve straight as shown in the lower curve of Fig. 12. The rectangular plot of these data is given in Fig. 13, including a greatly expanded initial

portion. It may be observed from this curve that the total strain at the time the load was fully applied is $\epsilon = 0.0080$. This is considered very good agreement with the value of 0.0070 determined graphically from Fig. 12. The small discrepancy between the two values may be due to the time-dependent strain which occurred during loading even though this represents a period of only 3.5 sec.

Thus it appears that the value of ϵ_0 obtained graphically is a real quantity having physical significance; i.e., it is the instantaneous total strain at the moment of loading, and the time-dependent strain, $\epsilon - \epsilon_0$, is linear on a logarithmic plot. Further evidence of this fact is presented in Figs. 14 and 15 which are replots of the curves of Figs. 6 and 7 in which the time-dependent strain only is plotted.

The relationship between strain and time of Eq 2 is further substantiated by the creep curves shown in Fig. 16 obtained from a series of solid solution nickel alloys. All of these specimens were tested at the same temperature and applied stress. It may be noted that the degree of curvature increases as the alloy content increases. However, when the instantaneous strain is subtracted from the total strain, all of these curves become linear as shown in Fig. 17. In these cases, the ϵ_0 was determined graphically. It should also be observed that the

Fig. 18—Effect of grain size on slope of logarithmic creep curves.

slope of the time-dependent strain curves, b in Eq 2, increases as the alloy content increases. Similarly, the slope varies with grain size as indicated in Fig. 18. Observations to date have not revealed any regular variation of b with applied stress and the variation with temperature is not clear at the present time. It may be noted from Fig. 5 that the slope, b , is essentially constant for all stresses from 3700 to 7200 psi at 700°C. Similar results have been found for tests carried out at 675°, 725°, and 750°C. All of these data yield a slope of $b \approx 0.3$ for pure nickel and progressively higher values as the solid solution alloy content is increased. The parameter A of Eq 2 on the other hand, does vary in a regular manner with stress and also varies with structure, alloy content, and temperature. This regular variation of A is illustrated in Fig. 19 in which the logarithm of A is plotted against $1/T$ for a series of pure nickel specimens tested in the temperature range 675° to 750°C. The value of b may be considered a constant for these curves. It may be seen that a straight line may be drawn through the data points with considerable accuracy, indicating that

Fig. 17—Time-dependent strain creep curves for Ni-Ti alloys.

Fig. 19—Variation of the parameter, A , with temperature.

A varies exponentially with temperature so that the following relationship may be written:

$$A = B e^{-Q/RT}$$

where: T is the absolute temperature; R , the gas constant; Q , the "experimental activation energy;" e , the base of natural logarithms; and B , a constant.

Since all of the foregoing data were obtained for polycrystalline materials, it was considered desirable to determine whether the continuously decreasing creep rate required the presence of grain boundaries. In order to resolve this question, creep data on zinc single crystals tested in shear were obtained from O.N.R. project workers of this laboratory. In the typical results shown in Fig. 20, the upper curve

Fig. 20—Logarithmic creep curves for zinc single crystal tested at 24.5°C and 35 psi.

(Fig. 20a) is the total strain and Fig. 20b is the time-dependent strain. It is apparent that single crystals also follow the behavior required by Eq. 2, indicating that the phenomena of continuously diminishing creep rate is not necessarily dependent upon the presence of grain boundaries.

Summary and Conclusions

Results obtained to date may be summarized as follows:

1—The creep rate for structurally stable metals tested under conditions of constant stress decreases continuously until the initiation of failure. There is no region of constant creep rate.

2—The creep curve may be accurately represented by the empirical equation:

$$\epsilon - \epsilon_0 = At^b$$

at constant temperature, or:

$$\epsilon - \epsilon_0 = Bt^b e^{-Q/RT}$$

over a considerable temperature range.

3—The parameter ϵ_0 is a quantity having real physical significance, denoting an instantaneous strain upon loading. The parameter A varies in a regular manner with stress and alloy content and exponentially with $1/T$. The parameter b also varies over a wide range but the correlation of b with temperature, stress, grain size, and alloy content will require many additional tests.

4—The empirical equation given is applicable to both single crystals and polycrystalline materials indicating that the continuously decreasing creep rate is not solely a grain boundary phenomena.

5—Accurate determination of the parameters A , b , and ϵ_0 requires strain measurements beginning at very short times after applying the load. In many cases readings must begin only seconds after loading.

Acknowledgments

The authors wish to thank the U.S. Atomic Energy Commission for sponsoring the work on which this paper is based and for permission to publish these data. We are sincerely appreciative of the conscientious work of Mrs. R. Hansen and her valued assistance in all phases of the work; we also want to thank Paul Langston for his careful work in the preparation of metals used in these tests and C. D. Nail for his valued assistance in the testing laboratory.

Some Observations on Correlations Between the Creep Behavior And the Resulting Structures in Alpha Solid Solutions

by Oleg D. Sherby and John E. Dorn

For elevated temperature-constant load creep tests of α solid solution alloys, the creep strain is a function of a temperature-compensated time parameter $\theta = \int e^{-\Delta H/RT} dt$. The activation energy ΔH is equal to a constant of about 36,000 cal per mol. The substructures resulting from a given creep stress condition are functions of the creep strain independent of temperature. Each new creep stress gives a new unique set of grain substructures; this is one of the factors responsible for the failure of the mechanical equation of state for creep.

IN this report an attempt is made to correlate the creep properties of dilute α solid solutions in aluminum with the subgrain structures that are developed during creep. The possibilities of such correlations have already been suggested by Wood et al. and others¹⁻⁶ who demonstrated that the subgrain structures are functions of the creep stress, creep strain, rate of creep, and temperature.

Investigations by Sherby and Dorn⁷ have shown that the creep strain, ϵ , at constant load for dilute α solid solutions of aluminum is given by the functional relationship:

$$\epsilon = f(\theta, \sigma_c) \quad [1]$$

where: θ equals $te^{-\Delta H/RT}$ = temperature-compensated time; t , time; ΔH , activation energy, $\sim 35,800$ cal per mol; R , gas constant; T , absolute temperature, above 400°K; and σ_c , initial creep stress.

Consequently, it was anticipated that the subgrain structure that develops during a constant load creep test should also correlate with any two of the three significant variables ϵ , θ , and σ_c .

Another possible correlation between the subgrain structure and the creep variables is obtained by differentiating Eq. 1 with respect to time, whence the creep rate, $\dot{\epsilon}$, becomes:

$$\dot{\epsilon} = \left(\frac{\partial f}{\partial \theta} \right) \left(\frac{d\theta}{dt} \right) = f'(\theta, \sigma_c) e^{-\Delta H/RT} \quad [2]$$

or:

$$\sigma_c = F(\dot{\epsilon} e^{\Delta H/RT}, \theta) \quad [3]$$

For the minimum creep rate, $\dot{\epsilon}_s$, θ is solely a function of σ_c as revealed by Eq. 1. Consequently, at the minimum creep rate Eq. 3 reduces to:

$$\sigma_c = F(\dot{\epsilon}_s e^{\Delta H/RT}) \quad [4]$$

Correlations between σ_c and $\dot{\epsilon}_s e^{\Delta H/RT}$ were found valid for solid solution alloys of aluminum where ΔH was a constant of about 35,800 cal per mol. The parameter $\dot{\epsilon}_s e^{\Delta H/RT}$ is identical to the Zener-Hollomon parameter^{8,9} used by them in evaluating the tensile properties of copper and other metals.

Table I. Composition of α Solid Solutions*

Alloying Element	Atomic Pct	Wt Pct of Impurities					Mean Grain Diameter, mm
		Si	Fe	Cu	Mg	Mn	
	(99.987)	0.003	0.003	0.006	0.001		0.25
Mg	1.617	0.003	0.004	0.006			0.26
Cu	0.101	0.003	0.003		0.0006	0.001	0.29

* The authors wish to acknowledge their indebtedness to the Aluminum Co. of America Research Laboratories for preparing these alloys and for determining their chemical compositions.

Eq. 4 suggests that the subgrain structure developed during secondary creep might be correlatable with either of the two variables $\dot{\epsilon}_s e^{\Delta H/RT}$ or σ_c .

Some of the solid solution aluminum alloys which were discussed in an earlier report⁷ were also used in the present investigation. Sheets of these alloys were homogenized, cold rolled from 0.100 to 0.070 in. in thickness and then recrystallized to about the same grain size. Their chemical composition and grain size are recorded in Table I. Creep specimens were selected with their tensile axes in the rolling direction. The details for creep testing have been described¹⁰ and will not be repeated here. All creep tests were performed under constant load conditions.

Experimental Results and Discussion

Metallographic Structure of Creep Specimens: In order to obtain a preliminary concept of creep on the metallographic structure of high purity aluminum, the various ruptured specimens previously used to obtain the creep data for pure aluminum were polished and etched electrolytically in a dilute solution of fluoroboric acid. Oblique illumination was used to reveal the substructures which, for convenience, are shown in correlation with the σ vs. $\dot{\epsilon}_s e^{\Delta H/RT}$ curve in Fig. 1. It is necessary to emphasize that the data for the curve refer to the various secondary stages of creep whereas the micrographs refer to the fractured creep specimens. Nevertheless a regular and systematic correlation is observed between $\dot{\epsilon}_s e^{\Delta H/RT}$ (or the creep stress) and the microstructure at fracture. For $\ln(\dot{\epsilon}_s e^{\Delta H/RT}) = 42.3$, which refers to creep at a high creep rate and a low creep temperature, the fractured aluminum specimen, as shown by the micrograph in the upper right-hand corner of Fig. 1, exhibited extensive deforma-

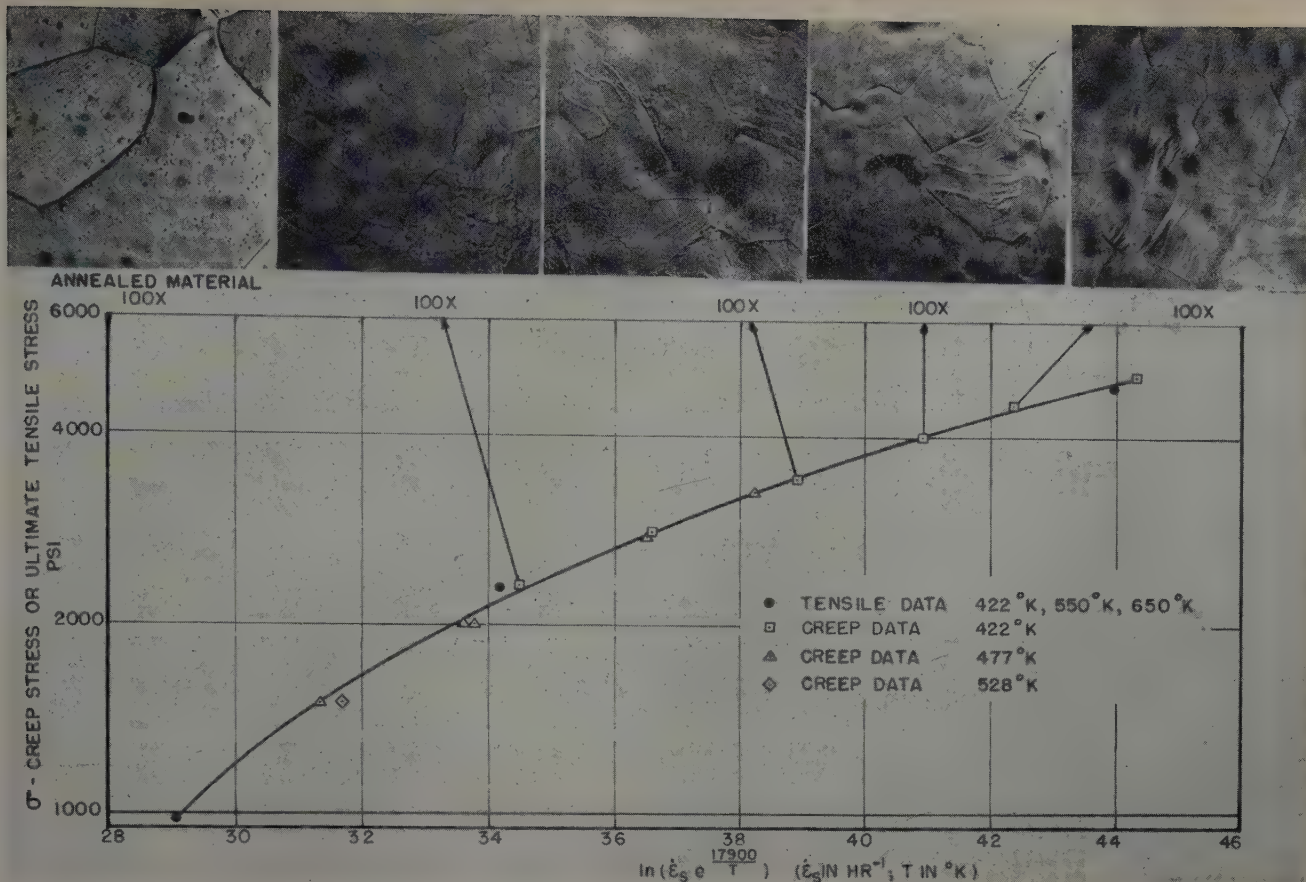

Fig. 1—Metallographic examinations of fractured creep specimens of high purity aluminum as a function of the parameter $\dot{\epsilon}_s e^{\Delta H/RT}$. Area reduced approximately 75 pct for reproduction.

tion banding. Such banded regions are distinguishable from the subgrain structures formed during creep at higher temperatures. This distinction will be more clearly revealed by the X-ray diffraction evidence which will be described in the following section.

At the opposite extreme where $\ln(\dot{\epsilon}_s e^{\Delta H/RT})$ was low, the micrograph of the fractured specimen was completely free from evidence of deformation banding. In lieu of deformation bands, the individual grains appeared to exhibit a fine polygonized structure. For intermediate values of $\ln(\dot{\epsilon}_s e^{\Delta H/RT})$ intermediate types of structures were obtained in the fractured specimens. Thus a regular trend was observed between the creep parameter $\dot{\epsilon}_s e^{\Delta H/RT}$ and the microstructure of the fractured specimens. Similarly, the metallographic structure of the fractured specimens appears to be a function solely of the creep stress, independent of the remaining test condition of temperature.

X-Ray Structure of Creep Specimens: The metallographic techniques necessary to reveal the substructures of creep specimens were found to be tedious and somewhat difficult for the Al-Mg alloy that was investigated. Consequently it was deemed advisable to obtain confirmation of the metallographic data by means of X-ray diffraction studies similar to those previously used by Wood and his colleagues.¹ For this purpose Debye-Scherrer back-reflection radiograms were taken of all the ruptured creep specimens of pure aluminum using a copper target tube operated at 40 kv. Representative samples of the various X-ray diffraction photographs for pure aluminum are reproduced in Fig. 2 and appropriately documented in terms of the creep or ultimate tensile stress and $\ln(\dot{\epsilon}_s e^{\Delta H/RT})$.

The X-ray structure of the original unstrained creep specimens used in this investigation is shown in the upper left-hand micrograph of Fig. 2. In view of the small pinhole (0.27 mm diam) relative to the grain size (0.25 mm diam) only a few grains contribute to the resulting diffraction spots. These spots are small and sharp, revealing that the original annealed specimen consisted of large, almost perfect strain-free grains. The fractured specimens for high values of $\ln(\dot{\epsilon}_s e^{\Delta H/RT})$ exhibited diffuse X-ray diffraction arcs somewhat typical of cold worked metals. These X-ray photographs are associated with the banded metallographic structure that was described in the previous section, and the arcing of the diffraction spot must be attributable to the range of orientations induced in a single grain due to lattice bending during creep. At the other extreme where $\ln(\dot{\epsilon}_s e^{\Delta H/RT})$ is small, the diffraction photographs of the fractured specimens clearly exhibit arcs consisting of a series of sharp, distinct diffraction spots. Undoubtedly each spot represents the diffraction from an almost perfect subgrain and the arc represents the range of orientations of the assemblage of subgrains which originated from one or, perhaps at most, two original grains. Thus X-ray diffraction evidence for subgrain formation at low values of $\ln(\dot{\epsilon}_s e^{\Delta H/RT})$ is directly correlatable with the confirming metallographic evidence which was described in the preceding section. Over the intermediate values of $\ln(\dot{\epsilon}_s e^{\Delta H/RT})$ a regular trend of the X-ray photographs of the fractured specimens were obtained, ranging from the diffuse Debye-Scherrer arcs for high values of $\ln(\dot{\epsilon}_s e^{\Delta H/RT})$ to sharp arcs composed of distinct spots for low values of $\ln(\dot{\epsilon}_s e^{\Delta H/RT})$, in complete harmony with the analo-

Fig. 2—X-ray back-reflection photograms of high purity aluminum as a function of the parameter $\epsilon_s e^{\frac{17900}{T}}$.

gous trends in the previously discussed metallographic structures.

The structure of fractured creep specimens appears to be a function of the creep stress independent of test temperature. The similarity in the diffraction photograms E and F and also G and H of Fig. 2 support this contention. The specimens whose diffraction photograms are reproduced in G and H were tested at the same stress at two different temperatures; they have about the same values of $\ln(\epsilon_s e^{\frac{\Delta H}{RT}})$ and, within the precision of the experimental techniques, they exhibit about the same diffraction effects. X-ray diffraction photograms E and F were obtained from fractured specimens subjected to only slightly different stresses at two different temperatures and they exhibited only slightly different values of $\ln(\epsilon_s e^{\frac{\Delta H}{RT}})$; they also reveal almost identical X-ray diffraction effects. Thus the structures and the creep properties of metals appear to be directly correlatable.

Effect of α Solid Solution Alloying on the Creep Properties and Structure: As shown by the creep data recorded in Fig. 3, the activation energy for creep is independent of dilute alloying additions.

The primary factor that is responsible for the improved creep resistance of α solid solutions probably arises from the slower crystal recovery rates induced by alloying.¹¹ This fact suggests that alloying elements restrain the migration of dislocations and therefore the α solid solutions should exhibit deformation banding down to somewhat lower values of $\ln(\epsilon_s e^{\frac{\Delta H}{RT}})$ than the pure element. The type of back-reflection X-ray photograms obtained from the series of fractured aluminum plus 1.6 atomic pct Mg creep specimens are shown in Fig. 4. Each photogram is documented in terms of the applied stress, temperature and $\ln(\epsilon_s e^{\frac{\Delta H}{RT}})$ to permit rapid comparison with the σ_c vs. $\ln(\epsilon_s e^{\frac{\Delta H}{RT}})$ data recorded in Fig. 3. The only significant difference between these correlations and those for high purity aluminum is discerned in the greater diffuseness of the diffraction arcs in the Al-Mg alloy for the same value of $\ln(\epsilon_s e^{\frac{\Delta H}{RT}})$.

Constant Load Creep Curves and Metallurgical Structure: In order to check more thoroughly the possible validity of Eq. 1, a series of three creep tests on three newly prepared specimens from a new sheet of high purity aluminum were made at 422°, 477°, and 528°K at a creep stress of 2000 psi. The results of these tests are given in Fig. 5. These tests correlate very well when the creep strain is plotted as a function of the temperature-compensated time. The obtaining of a slightly lower activation energy of $\Delta H \approx 17,000$ R cal per mol in lieu of the former value of $\Delta H \approx 17,900$ R cal per mol is probably attributable to a minor influence of sampling on the apparent activation energy. This difference however, is not conspicuous and will be disregarded for the present.

Fig. 3—Correlation of creep and tensile data of various aluminum solid solution alloys by the equation $\sigma \cong \sigma(\epsilon_s e^{\frac{17900}{T}})$.

Fig. 4—X-ray back-reflection photographs of an Al-Mg solid solution alloy as a function of the parameter $\dot{\epsilon}_s e^{\frac{17900}{T}}$.

The correlations obtained in Fig. 5 suggest that if long time creep data are desired for a given stress and temperature, they might easily be predicted from two short time creep tests at two somewhat higher temperatures. For the same strain on these two tests:

$$t_1 e^{-\frac{\Delta H}{RT_1}} = t_2 e^{-\frac{\Delta H}{RT_2}} \quad [5]$$

from which ΔH can be obtained. The same strain will be obtained for a creep test at the desired temperature, T , at time:

$$t = \frac{t_1 e^{-\frac{\Delta H}{RT_1}}}{e^{-\frac{\Delta H}{RT}}} = \frac{t_2 e^{-\frac{\Delta H}{RT_2}}}{e^{-\frac{\Delta H}{RT}}} \quad [6]$$

Thus it becomes a simple matter to calculate the entire creep strain, ϵ , vs time, t , curve for any temperature within the realm of validity of the temperature-compensated time concept.

The correlation mentioned between the creep strain and the temperature-compensated time suggests that the metallurgical structure should also correlate with the temperature-compensated time independent of the actual test temperature. In order to examine the validity of this concept, a series of creep tests were run under a creep stress of 2000 psi at each of the temperatures of 422°, 477°, and 528°K. At each temperature the specimens were removed for diffraction examination at the following strains: $\epsilon = 0.085, 0.15, 0.25$, and immediately following fracture. Since the creep curve at a given stress was shown to be a function of the temperature-compensated time, the constant strain values selected are identical with constant values of the temperature-compensated time. The strain $\epsilon = 0.085$ is approximately in the center of the primary creep interval; the secondary creep stage begins at about a strain of 0.15, and the tertiary stage begins at a strain of about 0.25 for the selected stress of 2000 psi. The X-ray diffraction photographs

which were obtained are shown in Fig. 6. Because of the limited number of grains which were sampled by the X-ray beam, small deviations were obtained in the diffraction patterns. Within the sensitivity of the diffraction technique, however, the same structures were obtained at identical strains for the various creep temperatures.

The substructure appears to be independent of test temperature for the same creep strain under a constant stress, but it changes markedly throughout the primary stage of creep. At a strain of 0.085 small diffuse Debye-Scherrer arcs are obtained, whereas at the conclusion of the primary stage longer and less diffuse Debye-Scherrer arcs are in evidence. Minor changes in the Debye-Scherrer arcs occurred over the secondary range of creep from $\epsilon = 0.15$ to $\epsilon = 0.25$ leading to slightly less diffuse and longer arcs. Additional metallurgical changes leading to less diffuse Debye-Scherrer arcs can be observed to occur over the tertiary stage of creep.

Fig. 5—Correlation of creep strain-time data of high purity aluminum by the equation $\epsilon \cong \epsilon(t e^{-\frac{17900}{T}})$ at a stress of 2000 psi.

Fig. 6—X-ray back-reflection photograms of high purity aluminum under a creep stress of 2000 psi for various temperatures as a function of strain.

As shown in Fig. 5, ϵ is a function of $te^{-\Delta H/RT}$ where ΔH is a constant, independent of temperature, over the entire creep curve; hence, it must be assumed that ΔH is independent of the structure over the entire range of structures revealed by the diffraction photograms in Fig. 6.

In view of the somewhat insensitive and qualitative nature of comparisons of the Debye-Scherrer photograms, some doubt might yet persist concerning whether exact identity of subgrain structures is achieved at identical strains, independent of the creep temperature, during constant load creep tests. Inasmuch as the plastic properties of metals are quite sensitive to their substructure, it was thought that unqualified proof of this thesis could be established by investigating the true stress-true strain curves at atmospheric temperatures following creep. The atmospheric temperature true stress-true strain diagrams of specimens precrept to the various structures previously recorded in Fig. 6 are shown in Fig. 7. As the creep strain of previously annealed specimens increases, the plastic properties at atmospheric temperatures improve, and the resulting stress-strain curves for constant load creep tests are iden-

tical for identical creep strains independent of the creep temperature. The thesis that the structural changes attending a constant load creep test depend only on the total creep strain independent of the creep temperature is therefore well established.

Creep Under Conditions of Variation in Temperature: In many technological applications the temperature under which creep occurs is not constant. It would indeed reduce the amount of testing if the creep curve for any prescribed program of temperature could be calculated from isothermal creep data. The basic correlations necessary for such a calculation are contained in the correlations between the creep strain and the temperature-compensated time. Assume that a metal is to be subjected to any arbitrary temperature-time history such as that given in the upper graph of Fig. 8. The activation energy can be obtained as outlined by Eq. 5 from two isothermal creep tests at the desired stress. Consequently the temperature-compensated time can be calculated from:

$$\theta_1 = \int_0^{t_1} e^{-\Delta H/RT} dt \quad [7]$$

Fig. 7—Tensile properties at 298°K following the series of creep histories shown in Fig. 6.

where T is the prescribed function of t . The value of the integrand of Eq. 7 is given in the second curve of Fig. 8. Thus the value of θ_1 for any time t_1 is merely the area under this curve from $t = 0$ to t_1 . The appropriate creep strain for the value of θ_1 can be read off of a chart based on the isothermal data, such as that given in Fig. 5. This sequence of operations can be repeated for other times until the entire creep strain vs time curve is predicted.

In order to test the above method of predicting creep for constant stress variable temperature conditions, two creep tests at 2000 psi were performed on high purity aluminum for the identical temperature history given in the upper curve of Fig. 8. The actual creep curves which were obtained are shown by the solid curves in the two lower graphs of Fig. 8; the predicted creep curves are illustrated by the dashed curves. The agreement is within the usual variations in creep data from sample to sample. Thus the practical utility of the concept of the temperature-compensated times is well established for the simple metallurgical systems which have been investigated here.

Creep and Resulting Structures: The success of the correlation of the creep strain in a constant stress test with the temperature-compensated time, as described previously, arises from the fact that the metallurgical structure is also a continuous function of the temperature-compensated time independent of the creep temperature. These correlations then allow the simple analyses of creep data for any temperature history. From both the theoretical and practical aspects of the problem on creep it is equally important to be able to describe the creep behavior of metals under any condition of stress history. By direct analogy with the problem of temperature history on the creep of metals, it is clear that the latter correlation would be readily feasible if the same metallurgical structures are developed in creep tests at various stresses. The complete solution of this problem has not yet been achieved but the results of some preliminary in-

vestigations, which will now be described, suggest that the resolution of the problem will be affected by several complicating factors.

The data contained in Figs. 2 and 4 clearly reveal a distinct difference between the structures of fractured creep specimens as a function of the creep stress. As shown in Fig. 1, specimens tested at the higher stresses exhibit deformation bands at fracture whereas those specimens tested at the lower stress levels exhibit a fine subgrain structure. Similar trends are observed in the X-ray diffraction photograms shown in Fig. 4. This suggests that the higher stress test specimens acquire a more severely deformed structure immediately upon loading, and due to their more rapid creep rate retain a more severely worked structure throughout their creep history; the less severely stressed specimens acquire an initially less deformed structure and exhibit greater grain perfection and recovery at the same values of the temperature-compensated time.

In order to study more thoroughly the differences in structures for creep tests conducted at different stress levels, a series of creep tests were conducted at two alternate stress levels 3400 and 2000 psi. Specimens were removed for X-ray diffraction studies at strains of 0.085, 0.15, 0.25, and at fracture. The higher stress tests exhibited greater initial deformation and continued to exhibit such greater deformation at the same strains and same values of the temperature-compensated time throughout the entire creep history. Also, at no point in the higher stress tests was a structure achieved which was in any way similar to the structures obtained at the lower stress level. These observations, then, reveal one source of

Fig. 8—Predicted and experimental creep curves for high purity aluminum when the temperature is changed as a function of time under constant load conditions.

Fig. 9—Effect of change of stress on the creep of high purity aluminum.

the failure of the mechanical equation of state for creep.

If at some stage in a low stress creep test the stress is suddenly increased, the additional tensile deformation that results will introduce changes in the structure of the specimen, bringing the structure into closer agreement with that obtained at some stage of the higher creep stress test. But inasmuch as the structural changes that are introduced upon increasing the load are superimposed on the substructure obtained during creep at the originally lower stress, it is improbable that the resulting structure will coincide exactly with that obtained at any stage of creep in a specimen subjected exclusively to the higher stress. Thus the past stress history modifies the structure of metals in such a way as to modify their subsequent mechanical properties. These discussions are also pertinent to cases wherein the stress is lowered at some stage of creep. The instant the stress is lowered the structure remains essentially that which was developed at the higher stress excepting for the minor modifications induced by creep recovery. At the lower stresses this structure might undergo crystal recovery and polygonization so that eventually the structure begins to approximate that of a specimen exclusively subjected to the lower stress. But inasmuch as the structure upon lowering the stress is reasonably different from that of any structure which is developed exclusively at the lower stress, it is unlikely that exact coincidence of structure can be achieved. The creep data recorded in Fig. 9 illustrate this point. The solid squares refer to creep of high purity aluminum under 3400 psi at 422°K, whereas the solid triangles refer to creep under 2000 psi at the same temperature. A third creep test was conducted at 3400 psi, represented by the open squares, and then the stress was lowered to 2000 psi, represented by the open triangles. The small differences in the solid and open square data for 3400 psi are attributable to sampling differences. After the stress was lowered to 2000 psi a very low creep rate was obtained. The shape of the 2000 psi curve for the specimen prestressed at 3400 psi is very dissimilar from the shape of the curve for the specimen stressed exclusively at 2000 psi. This implies that the structure of the specimen prestressed at 3400 psi probably never achieves the same structure developed in the specimen stressed exclusively at 2000 psi.

Conclusions

1—For α solid solution alloys the creep strain for a constant stress creep test is a function of the temperature-compensated time $\theta = \int e^{-\frac{\Delta H}{RT}} dt$ where: t is the time; T , the test temperature, °K; R , the gas constant; and ΔH , the activation energy.

2—The activation energy for high temperature creep is relatively insensitive to the test temperature, stress, grain size, small concentrations of alloying elements, and metallurgical structure of α solid solutions. ΔH was found equal to approximately 35,800 cal per mol.

3—If the creep curves for a constant stress are known for two temperatures, ΔH can be evaluated. Using this value of ΔH , the creep strain vs time curve can be calculated for any variable high temperature program for creep.

4—The creep behavior of α solid solutions is directly correlatable with the grain substructures that are developed. For a given creep stress the substructures are functions of the creep strain independent of the test temperature.

5—For each new creep stress a unique set of grain substructures is developed as a function of creep strain. This is one of the factors responsible for the failure of the mechanical equation of state for creep.

Acknowledgments

This investigation was sponsored by the Office of Naval Research. The authors wish to thank the ONR staff for their continued interest and full cooperation throughout the conduct of this and related studies on the plastic properties of aluminum alloys. The materials used were supplied by the Aluminum Research Laboratories together with their chemical analyses.

In addition the authors wish to thank Stewart Frederick and Warren Giedt for assistance in the X-ray and creep testing programs, M. Kawaguchi for the micrographic pictures, and C. Dean Starr for his interest in and contribution to this study. To G. Pelatowski sincere appreciation is extended for her careful preparation of the figures in this report.

Creep Properties of Commercially Pure Titanium

by W. R. Kiessel and M. J. Sinnott

The creep characteristics of commercially pure titanium sheet in the annealed state, cold-worked state, and cold-worked and recovered state in the temperature range from 75° to 750°F have been determined. Titanium has been found to exhibit strain aging characteristics. The effect of strain aging on creep has been determined. A possible explanation for the poor creep properties of titanium is proposed.

THE metal titanium exhibits many desirable properties but results on its creep properties have been somewhat disappointing. The creep strength is low even though the material has a very high melting point.¹ The present work was undertaken to determine the creep strength of titanium in various conditions; annealed, cold-worked, and cold-worked and recovered and to determine why titanium shows such relatively poor creep properties.

The general procedure followed in this research consisted in obtaining the usual mechanical prop-

erties such as creep strength, short time tensile strengths, and hardness on materials treated to a controlled degree of internal strain, as determined by X-ray diffraction measurements, and their subsequent interpretation in terms of this internal strain.

The material used in this work was sheet stock taken from one heat of commercially pure titanium. As-received, this sheet was 0.060 in. thick. The analysis was given as 0.037 pct C, 0.023 pct Si, 0.50 pct W, 0.063 pct Ni, 0.08 pct Fe, and the remainder titanium. The oxygen and nitrogen were unreported but generally are about 0.2 pct in commercial heats.

In order to put the material in a state of minimum internal strain all the sheet was given an anneal in a static argon atmosphere for 1 hr at 1600°F prior to processing and testing. The microstructure of the material after this treatment was essentially a single-phase solid solution of uniform equiaxed grains.

For the studies on the cold-worked sheet, the material was reduced by rolling in a two high, 5 in. mill. Rolling was done at room temperature in passes

Fig. 1—Effect of cold working on the integrated intensity of the diffracted (002) X-ray line.

of not more than 10 pct reduction per pass, the material being cooled after each pass.

In determining the recovery characteristics of the cold-reduced stock, the material was annealed at temperatures of 210°, 400°, and 600°F for time intervals of 1, 100, and 1000 hr. All creep and tensile specimens were annealed or treated in a similar manner. Specimens that were treated at other temperature levels will be indicated.

Test Procedures

Tensile test and creep data at room temperature were obtained by the use of electric strain gages. For elevated temperatures a modified Martens extensometer was used. Strain rates of 0.001 and 0.050 in. per in. per min were used in taking the tensile data. All tests were run in air and temperatures were controlled to $\pm 3^\circ\text{F}$ as measured by thermocouples attached to the specimens. In the creep tests the specimens were placed in a furnace operating at the test temperature and, after thermal equilibrium was established, the load was applied through a lever

Fig. 2—Pictorial description of preferred orientation correction of integrated intensity measurements for sheet textures.

system which placed the material under constant stress rather than constant load. In most cases complete time-elongation data were obtained but in some instances readings could not be taken until 0.1 hr had elapsed, due to the abnormally large first-stage creep component. Total strain was measured in all cases but is not reported in this paper. Creep test durations were on the order of 1000 hr. In some cases this time interval was insufficient for steady state creep conditions to be reached and in those cases the minimum rate was taken as the steady state creep rate. Longer duration tests showed that this introduced only a small error in the creep rates. The least creep rate obtainable was dictated by the accuracy of the extensometer system, 3×10^{-6} in. per in., and the maximum rates by the rupture properties of the metal.

X-ray diffraction studies using $\text{CuK}\alpha$ radiation were made on etched surfaces of the titanium sheet, the diffracted beam being filtered. For line intensity

Fig. 3—Effect of cold work on the internal strain as measured by the line breadth of diffracted (114) beam.

measurements the (002) line, $2\theta = 38.8^\circ$, was studied using a Norelco spectrometer with a Geiger-Mueller tube and counting circuit to record the diffracted energy. Orientation corrections were made on these specimens by determining the integrated intensity distribution in all positions with a Shultz fixture.² This is essentially the method used by Frey³ after modification for sheet textures. Diffracted line breadth studies were made on a high angle Norelco spectrometer on the (114) planes, $2\theta = 114.6^\circ$, which were aligned parallel to the rolling direction.

Corrections for instrumental broadening were made on all spectrometer traces by the use of Fourier analysis.⁴ Generally ten harmonics were used although in cases of small strain the number was extended to as many as twenty. As a measure of the amount of line broadening, and hence the amount of internal strain, the breadth was determined in units of radians at the half peak.

Internal Strain Measurements

Mechanically working a metal can result in two phenomena occurring in the lattice; fragmentation^{5, 6} and changing of the interplanar spacings.^{7, 8} Both of these processes can cause broadening of the X-ray diffraction beam. Fragmentation, however, will cause no appreciable broadening unless the crystallites are 10^{-5} cm or less in thickness.⁹ Since line broadening is used in this work to determine the internal strain or changes in interplanar spacings,

Fig. 4—Effect of cold work on the diamond pyramid hardness of rolled titanium sheet.

it was necessary to evaluate the fragmentation effect if it existed. This was done by the use of integrated intensity studies. The amount of fragmentation that has occurred will be reflected in the degree of primary extinction.

Primary extinction, the power loss of a diffracted beam due to the rediffraction of energy in any one fragment, can be expressed by means of the Darwin term applied to the integrated intensity of the diffracted beam.¹⁰ It is stated as follows:

$$P' = P \frac{\tanh(\text{Constant} \cdot \csc 2\beta \cdot F_{hkl}^2 \cdot d^3 \cdot \cot \beta)^{1/2}}{(\text{Constant} \cdot \csc 2\beta \cdot F_{hkl}^2 \cdot d^3 \cdot \cot \beta)^{1/2}}$$

where P is the integrated intensity of an extinctionless sample; P' , the corrected integrated intensity; β , Bragg angle; F , the structure factor; and d , the thickness of the mosaic fragment.

The correction term approaches unity as d , or β approach zero. If a measurable increase of the integrated intensity of an X-ray diffracted beam occurs at a given Bragg angle from samples cold-worked to various degrees, then the fragment size is such as to cause no broadening of the diffracted beam.

Test pieces of annealed titanium, and sheet rolled 13, 40, and 60 pct were analyzed using the (002) line. The results, as presented in Fig. 1, showed that the integrated intensity of this line, after corrections for preferred orientation effects, increased quite markedly over the entire range, thus indicating that the particle size was not contributing to the broad-

Fig. 5—Effect of recovery time and temperature on internal strain, as measured by line breadths, for titanium cold-reduced 40, 12, and 7 pct.

ening of the diffracted beam. Such broadening as did occur, less instrumental effects, was due to internal strain. This is in general agreement with Smith and Stickley¹¹ and Brindley and Ridley¹² although their investigations were carried out on metallic powders.

The method used for the orientation corrections of the diffracted line integrated intensity measurements can best be explained by reference to Fig. 2. Consider a specimen arranged as shown in Fig. 2a. The X-ray primary beam, which strikes the specimen at the Bragg angle θ , and the diffracted beam lie in the same plane as the axis A-A. If the specimen is rotated to various angular positions α , about A-A, and the integrated intensity measurements made, all the (002) planes lying parallel to the axis will have a chance to diffract. Similarly, if the specimen is rotated about the specimen normal N , to angular position β , as C-C, between A-A and B-B, and if at each such position the specimen is rotated about C-C, as was done about A-A, then all the

Fig. 6—Effect of recovery time and temperature on the diamond pyramid hardness of titanium rolled 40, 12, and 7 pct.

(002) planes can be accounted for. A series of plots as shown in Fig. 2b, one for axis A-A, axis B-B, and each β angular position of C-C, can be drawn. Combining these plots gives a volume as shown in Fig. 2c, and from the volume an average integrated intensity can be found.

Since titanium exhibits a symmetrical pole pattern, the intensity distribution was determined in one quadrant only; the determinations being made for 15° increments in β and 5° and 10° increments in α . No extinctionless standard was available for absolute intensity or extinction measurements. The relative values, however, were sufficient for this investigation.

Line Breadth Studies

Since broadening of the diffracted X-ray line was found to be caused by internal strain, the effect of varying amounts of cold working on the state of the internal strain was measured. As shown in Fig. 3, cold work up to 30 or 40 pct produces the near maximum of internal strain; further working resulting in only a slight increase, but this is followed by a decrease because of the onset of self-recovery. The data shown in Fig. 3 were taken within 6 hr of rolling. Additional aging at room temperature for four months showed recovery occurring only in specimens reduced 60 pct or more. These facts, coupled with the difficulty of testing thin sheet

Fig. 7—Second-stage creep rate at 76°F of annealed and cold-reduced titanium sheet as a function of stress.

specimens, resulted in the selection of 40 pct cold work as being the maximum state of internal strain in subsequent studies.

For comparative purposes the effect of cold working on the diamond pyramid hardness is shown in Fig. 4. Its response to changes in internal strain is less sensitive than the X-ray procedure. A metallographic examination of the cold-worked samples showed an elongation of the grains but no deformation bands or twins.

Recovery Studies

The recovery process in cold-rolled titanium was observed by X-ray line breadth measurements and by hardness determinations. Sheets rolled 7, 12, and 40 pct were recovered at temperatures of 210°, 400°, and 600°F for time intervals of up to 1000 hr. The results of the line breadth measurements are shown in Fig. 5, while Fig. 6 shows the results of the hardness measurements.

Recovery did not occur at 210°F on the titanium reduced 7 pct and was incomplete on the sheet reduced 12 and 40 pct. A constant value of internal strain for each condition of previous cold work was reached after 20 to 50 hr at either 400° or 600°F. The hardness measurements showed the same trends as the line breadth studies but did not respond as readily.

Creep Studies

Creep tests were conducted on the annealed, the cold-worked, and the cold-worked and recovered

Fig. 8—Correlation between line breadth and second-stage creep rate at 76°F of annealed and cold-reduced titanium at various stress levels.

titanium. Fig. 7 is a plot of the stress vs second-stage creep rate for tests conducted on the annealed stock at 76°F.

Line breadth studies conducted on these completed creep specimens showed only a slight change in internal strain. These increases can be attributed to strain hardening. The specimens tested under high strain rates showed between 5 and 6 pct total elongation after testing. Measurements of the internal strain in these specimens, when compared with the internal strain of samples rolled to this extent, were identical.

The effect of varying degrees of cold work on the creep rate of titanium at 76°F is shown in Fig. 7. Small amounts of cold work are more effective in increasing the creep resistance from the annealed state than from higher degrees of cold work. This follows the trend developed in the internal strain measurements vs cold work, as shown in Fig. 3.

Fig. 8 shows that a logarithmic relationship exists between the line breadth measurements made prior to testing and the creep rate developed at 76°F on the stock cold-reduced to varying degrees. This correlation appears to be valid regardless of the stress level considered. Some of the annealed material shows higher creep rates than would be

Fig. 9—Second-stage creep rate at 76°F of titanium sheet cold-worked 40 pct and recovered 100 hr at various temperatures.

Fig. 10—Short-time tensile properties of annealed titanium sheet as a function of temperature.

Fig. 11—Diamond pyramid hardness at room temperature of completed short-time tensile specimens.

predicted from a consideration of the cold-worked material only. The reason for this is that the true second-stage creep rate was not reached in the time interval used. Other tests for periods up to 2300 hr (see 44,600 psi data of Fig. 8) yielded data which agree with the correlation obtained on the cold-worked stock.

Fig. 9 presents the results of the creep studies at 76°F on titanium cold-worked 40 pct and recovered 100 hr at temperatures of 210°, 400°, 550°, and 750°F. It will be noted that the creep resistance does not decrease with increasing recovery temperature. Instead the creep strength increases as the recovery temperature increases and reaches a maximum at 400°F.

No correlation between internal strain, as measured by line breadths, and the creep properties at 76°F was obtained on these cold-worked and recovered samples. It is believed that the redistribution of the internal strains during recovery is such as to cause a strengthening effect which is greater than would be predicted from the line breadth measurements.

Strain Aging

The inversion that occurred in the creep properties of the cold-worked and recovered samples is believed to be due to strain aging, since no evidence could be found metallographically for the presence of precipitation. Since strain aging is generally indicated by the following characteristics of: 1—general strengthening, 2—yield point phenomena, 3—decreased strain rate sensitivity in the region of strengthening, and 4—a serrated stress-strain curve,¹⁴ these criteria were investigated by making short time tensile test studies on the annealed material. The studies were made at strain rates of 0.001 and 0.050 in. per in. per min at temperatures to 1000°F. At the faster strain rate it was not possible to determine the stress-strain curves and the yield strengths were not obtained. Fig. 10 summarizes the mechanical properties as determined by these tests. The data show that there is a decrease in tensile strength with increasing temperature but in the range of 600° to 800°F the tensile strengths are constant while the elongation decreases. Over the same temperature range the strength is approximately constant regardless of the strain rate. This is not the case at higher or lower temperatures. An examination of the stress-strain curves showed the presence of a yield point in the tests conducted at temperatures from 210° to 650°F and the presence of serrations. In view of these data, it is concluded

that the titanium tested is subject to strain aging. The basic cause is as unknown as in any of the other metals in which this phenomenon has been detected. The same elements which are variously believed to cause the effect in other metals are present in the titanium, namely, carbon and nitrogen.

In order to obtain some indication of the order of increase in hardness attributable to strain aging, measurements were taken on the completed tensile specimens 1½ in. from the fracture. The results are shown graphically in Fig. 11. The greatest hardening occurred at the lower temperatures because of strain hardening. Increasing temperatures caused a decrease in the strain hardening component, but in the range of 600° to 800°F strain aging is present and its effect must be added to the effect of strain hardening. If it is assumed that the strain hardening component follows the dotted line of Fig. 9, then the maximum hardness increase that can be caused by strain aging is approximately 8 DPH.

Elevated Temperature Creep Tests

Fig. 12 is a plot of the stress vs second-stage creep rate for the annealed titanium tested at 210°, 400°, 600°, and 750°F. These data show that the creep resistance does not continue to decrease with increasing temperature, as might be expected, but instead show a maximum at 400°F. Fig. 13 is a cross-plot of the effect of temperature on the stress required for a given creep rate and more clearly shows this effect.

An interesting feature was noted in the time-elongation curves of these tests. Generally the elevated temperature tests yielded long sweeping

Fig. 12—Second-stage creep rate of annealed titanium sheet as a function of stress and temperature.

Fig. 13—Effect of temperature on the stress to cause a creep rate of 10^{-6} per hr in annealed titanium sheet.

Fig. 14—Second-stage creep rate as a function of stress and temperature for titanium sheet cold-worked 40 pct.

Fig. 15—Effect of stress and temperature on the second-stage creep rate of titanium sheet cold-reduced 40 pct and recovered at various temperatures.

curves with the true second-stage creep rate being established very late in the testing period. In the tests conducted at 400°F however the second stage of creep was established much sooner. At any one stress level the total amount of extension at 400°F was greater than at 210°F because of the higher initial plasticity, but the second-stage creep rate at 400°F was established sooner and was less because of strain aging.

Line breadth studies and hardness measurements were made on the completed creep test specimens of the annealed material tested at elevated temperatures. The results showed that there was an increase in internal strain in the material due to the testing. Some of this strain is due to strain hardening but the samples tested at 400°F had a higher residual internal strain than corresponding specimens tested at the same stress at 210°F. Strain aging is believed to be the cause of this increase.

The maximum effect of strain aging occurred at approximately 400°F, regardless of how it was induced. The increased creep resistance of the annealed and the cold-worked and recovered titanium at the temperature of 400°F is analogous to the increased tensile properties noted at 600°F of Fig. 10. The difference in temperature for the maxima in the two tests can be explained on the basis of the work of Nadai and Manjoine.¹⁵ They showed that with increased rates of straining the temperature of the strain-aging effect is raised and that the extent of the effect is diminished.

The results of creep testing titanium cold-worked 40 pct at elevated temperatures are shown in Fig. 14. The cold-worked material has a higher creep

resistance than the annealed material tested at the same temperatures (see Fig. 12). As the temperature of testing is increased, the creep resistance of the cold-worked material decreases regularly. A possible explanation for the behavior of this material is that the cold working introduces internal strain which strengthens the matrix. During testing at elevated temperatures recovery occurs and this decreases the strength, but the higher temperatures also induce strain aging which strengthens the material. The net result of these last two processes is that essentially they nullify one another.

In the static recovery tests, a constant state of internal strain was reached after approximately 40 hr at temperature. This was not true on materials recovered under stress, since internal strain measurements and hardness measurements on cold-worked 40 pct completed creep specimens tested at elevated temperatures showed values that were lower than the values obtained on the samples recovered under no-load conditions.

In order to study the effect of strain aging induced prior to creep testing on the creep characteristics of titanium, a set of specimens cold-worked 40 pct was recovered at 400° and 550°F prior to testing at temperatures to the recovery temperature. The results are summarized in Fig. 15. Recovery at 400°F produced the greatest strain-aging effect on the creep resistance at 76°F (see Fig. 9), so it was assumed that the same treatment would result in the best creep properties at elevated temperatures; an assumption that is verified in tests at 210°F as shown in Fig. 15. When, however, the material was tested at the same temperature as the temperature of recovery, the strength decreased due to the addi-

Fig. 16—Effect of stress and recovery time on the second-stage creep rate at 76°F of titanium sheet cold-worked 40 pct and recovered at various temperatures.

tional recovery taking place under stress. As verification of this, the treatment of a specimen cold-worked 40 pct and recovered 100 hr at 440°F was sufficient to prevent any further recovery during subsequent testing at 400°F. The internal strain measurements and hardness measurements made on the above specimens showed that there was no change in these parameters as long as the creep testing temperature was below the temperature used for the prior recovery.

In order to determine the effect of time, as well as temperature, on the strain-aging process, titanium cold-worked 40 pct was recovered 1, 10, and 100 hr at temperatures of 210°, 400°, and 550°F and creep tests made at 76°F. The results are shown in Fig. 16. The results are more graphically illustrated in Fig. 17 where the stress necessary to produce a creep rate of 10⁻⁷ per hr at 76°F is plotted against the log of the time at the recovery temperature. The results are typical of an aging process.

Tensile tests at 76°F were made on the material cold-worked 40 pct and recovered at 400° and 550°F

Fig. 17—Stress required to cause a second-stage creep rate of 10⁻⁷ per hr at 76°F in titanium sheet cold-reduced 40 pct and recovered at various temperatures for indicated times.

for varying time periods. The results, shown in Fig. 18, parallel those of the creep data and a correlation between these tensile strengths and the creep resistance for a constant stress was found to exist as shown in Fig. 19. Similar tests on the material cold-worked 40 pct and recovered 100 hr at 210° and 750°F were made and the results agreed with this correlation.

Strain aging has a marked effect on reducing the amount of overall extension by reducing the transient creep component. This fact is quite vividly shown by comparing the total extension at 76°F of specimens cold-worked 40 pct and cold-worked 40 pct and recovered 100 hr at 550°F prior to testing. These two materials had the same second-stage creep component but the strain-aged material had only one-half the total extension, after 1000 hr under test at the same stress, as the cold-worked stock.

Applications of Creep Theories

Andrade¹⁶ has found that creep is mainly of the transient type if the test temperature is low relative to the melting point of the metal and mainly of the quasi-viscous type if the test temperature is high relative to the melting point of the metal. It was thought that at 76°F titanium might exhibit mainly transient creep and this hypothesis was supported qualitatively by the behavior of the annealed ma-

Fig. 18—Effect of time and temperature of recovery on the tensile properties of titanium sheet cold-worked 40 pct.

terial, since quasi-viscous or second-stage creep was not always reached in the time interval considered. An attempt was made, therefore, to correlate existing theories of transient creep with the data collected at 76°F on the annealed and on the cold-worked materials. The data were examined in accordance with the Orowan theory of transient creep,¹⁷ the modification of Smith,¹⁸ and the theory of Mott and Nabarro¹⁹ by noting the mathematical relationship existing between time and strain. In no case did the existing theories describe the creep behavior found for titanium. Deviation from the predicted curves occurred after a time interval of from 50 to 200 hr, depending on the theory and material under consideration. It would seem that second-stage creep becomes active after a relatively short testing time and any further consideration that titanium exhibits chiefly transient creep at room temperature is fallacious.

The analysis of the second-stage creep component was made in accordance with the rate process theory of Eyring and others.²⁰ The process, according to this theory, is assumed to be the result of the activation of small units of flow and their subsequent movement under the applied shear stress over energy barriers. These considerations lead to the following equation:

$$\dot{\epsilon} = \text{Constant} \times T \times e^{\Delta S/R} \times e^{-\Delta H/RT} \times e^{qV\sigma/kT}$$

where $\dot{\epsilon}$ is the creep rate; T , the absolute temperature; σ , the applied stress; S and H , the entropy and enthalpy of activation process; R and k , constants, gas and Boltzmann; V , the flow volume; and q , the stress concentration factor.

Fig. 19—Correlation between the tensile strength at 76°F and the second-stage creep rate at 76°F under a stress of 60,000 psi of titanium sheet cold-reduced 40 pct and recovered at various times and temperatures.

The usefulness of the theory lies in the fact that, by fitting it to experimental data, some idea of the values of ΔH , ΔS , and V can be determined for comparative purposes.

The flow volume, V , can be determined if several assumptions are made; namely that ΔH and ΔS are not functions of stress and that q is approximately unity. The above equation then reduces to:

$$\log \dot{\epsilon} = \log C_1 + V\sigma/2kT$$

From a plot of the log of the creep rate at 76°F vs stress the slope was found for the materials worked 0, 7, 12, and 40 pct and the values of V found. They varied from 148Å³ to 90Å³ in going from 0 to 40 pct cold work. This is the same order of magnitude as those reported for brass and extrapolated for steel and about ten times less than those reported for zinc.²¹

An estimation of ΔH can be made by plotting C_1 vs $1/T$ since,

$$C_1 = \text{Constant} \times T \times e^{\Delta S/R} \times e^{-\Delta H/RT}$$

It was assumed that temperature has little effect on ΔH over the range considered. The instability of the material prevented the use of data taken above the range of 76° to 210°F. The ΔH for the annealed titanium was found to be 3550 cal. The value of ΔS , as determined graphically, was -99.4 cal per degree per mol.

Combining ΔH and ΔS , as in equilibrium theory, a value of ΔF can be obtained for the free energy of activation. For the annealed titanium a value of 33,000 cal per mol results. This is in the range of values encountered in the soft metals such as tin, zinc, and lead; the ΔF values for steels are greater, being on the order of 50,000 cal per mol.

A similar analysis of the creep data taken on the material cold-worked 40 pct gave a ΔH value of 3000 cal per mol, a ΔS of -105 cal per degree per mol, and a ΔF of 34,500 cal per mol. Obviously there is little difference between the thermodynamic properties of the annealed and cold-worked titanium and the differences in properties between the two states are attributed to the size of the flow volume.

In view of the above, the following generalized statements can be made. Although the free energies of activation are approximately the same for titanium and the soft metals, which have poor creep resistance, titanium is somewhat superior due to its smaller flow volume. On the other hand, titanium and steels have the same flow volume, but the higher free energy of activation of the steels gives them better creep properties than the titanium.

The correlation of internal strain, as measured by X-ray line width studies, with the creep properties of the titanium is not an unexpected phenomenon. Another form of the Eyring rate equation might be as follows:

$$\dot{\epsilon} = \text{Constant} \times T \times e^{\Delta S/R} \times e^{-\Delta H/RT} \times e^{qV(\sigma - \sigma_i)/KT}$$

where σ_i is introduced to describe the internal stress caused by cold working; the other terms are as described previously. This relationship allows for the introduction of internal stresses into the material which oppose the externally applied stress. If, for a constant applied stress and a constant temperature, ΔS and ΔH can be assumed as constant, an assumption that appears to be valid, then the above equation can be reduced to:

$$\log \dot{\epsilon} = \text{Constant} - \text{Constant} \times \sigma_i$$

This is the relationship actually found and graphically shown in Fig. 8.

Conclusions

1—Cold working commercially pure titanium sheet, up to 40 pct by rolling, improves the creep resistance because of the residual strains left in the lattice.

2—Recovery of titanium sheet rolled more than 60 pct occurs at room temperature; sheet rolled 40 pct, between room temperature and 210°F; sheet rolled 7 pct, between 210° and 400°F.

3—Titanium sheet exhibits strain aging.

4—Strain aging markedly improves the creep resistance.

5—A correlation exists between the amount of internal strain induced by cold rolling, as measured by X-ray prior to testing, and the creep resistance at temperatures below which recovery occurs.

6—There appears to be a correlation between the short time tensile strength and creep resistance for titanium which has been cold-worked and recovered.

7—Cold working and/or strain aging reduces extensively the amount of first-stage creep.

Occurrence of Chi Phase in Molybdenum-Bearing Stainless Steels

by P. K. Koh

Chi phase (body-centered cubic, $a = 8.89\text{\AA}$) was found in as-cast 23 pct Cr-10 pct Mo-Fe alloy as well as in heat-treated 316, 316L, 317, and modified 446 stainless steels. Chi phase resembles sigma phase in its metastability, chemical composition, and brittleness. Microstructure and some of physical properties of chi phase were developed.

MOLYBDENUM has been established as a desirable alloying element for the enhancement of corrosion resistance in Cr-Ni steels and creep and rupture strength in high temperature alloys. On the debit side, however, the molybdenum addition has been known to stimulate σ formation. When the molybdenum-bearing steels were subjected to prolonged heating at elevated temperatures, losses of corrosion resistance and/or ductility have been observed.

Andrews^{1,2} first found the existence of a new phase among the anodic FeCl_3 extracts from type 316 stainless steel solution treated and then reheated from 800° to 1100°C . This phase was designated χ and was identified by diffraction patterns as of body-centered cubic structure with a value equal to 8.89\AA and similar to that of α manganese. He found that the χ phase in this steel always coexisted with σ phase, but failed to distinguish one from the other by metallographic technique. No definite conclusion was drawn regarding the equilibrium temperature ranges of these two phases.

The appearance of Andrew's work recalled an un-

explained structure observed several years ago at the Allegheny Ludlum Research Laboratories during the investigation of an experimental alloy containing 25 pct Cr, 10 pct Mo, and balance Fe. X-ray diffraction patterns on the as-cast material revealed the presence of a body-centered cubic phase having a lattice parameter of 8.89\AA . The structure was sufficiently similar to that of γ chromium that for a time it was thought that the structure might be caused by the presence of some undissolved electrolytic chromium particles. The alloy as-cast was so brittle that it shattered after the slightest hot reduction by hammer cogging.

This paper gives the results of some metallographic and X-ray diffraction studies on χ phase as found in several experimental alloys as well as a few molybdenum-bearing commercial stainless steels. The analyses of materials studied were as shown in Table I.

Experimental Procedure

Metallography: Solid specimens were polished mechanically and etched in boiling 50 pct HCl solution in order to best delineate χ and σ phases in the alloys studied.

X-Ray Diffraction: The difficulty of satisfactorily developing diffraction lines for σ phase in solid specimens has been previously reported by Bindari, Koh, and Zmeskal.³ For this reason all specimens used in this investigation were subjected to anodic

extraction in ferric chloride solution. X-ray studies were carried out on the extracted residues.

A wedge powder specimen was adopted for the Debye camera because of convenience in preparation. Accurate determination of lattice parameter was found to be difficult due to absorption of the diffracted beam by the wedge specimen and because of mechanical difficulties in centering the specimen in the camera. Lattice parameters are therefore reported to only two decimal places.

Electrolytic Extraction: The electrolytic extraction cell consisted of an alundum crucible, a 3000 cc beaker, an 18-8 stainless steel sheet cathode with the specimen as anode. Copper lead wires were soldered onto both anode and cathode, the soldered joints being covered with paraffin. The cathode was placed inside the alundum crucible which rests on the bottom of the beaker. The anode is placed outside the alundum crucible which serves as a diaphragm to prevent the extracted residue from being contaminated by the reaction products formed around the cathode. The pH value of the FeCl_3 electrolyte varied between 1.1 at the beginning to 0.1 toward the end of a run. The electrolyte dissolved the matrix at a reasonable rate depending upon the exposed area of the anode and the voltage drop across the cell. The extract was recovered by filtering through a frit-glass bottom filter, and was subsequently dried at 220°F.

Heat Treatment: Specimens were protected from oxidation during heat treatment by electroplating

with chromium. Specimens $\frac{1}{4}$ in. thick were cut from ingots or bars of the alloys under study for metallographic examination and extraction after heat treatment.

Occurrence of Chi Phase

Iron-Base Alloys: Fe-Cr-Mo Experimental Alloys: Experimental heats CM 68 and CT 60 were melted as part of an independent investigation of the resistance of certain alloys to attack by molten metals. When attempts were made to forge the alloys, they both cracked under light hammer blows. The explanation of the observed hot-shortness lay in the presence of χ phase as shown in the microstructures of Figs. 1 and 2.

While both heats exhibited the presence of χ phase (Table II), in heat CT 60 the phase was inclined to

* Phases present are listed in the order of decreasing line intensity.

be somewhat more nodular. Additional quantities of χ phase were precipitated from the ferritic matrix on reheating to temperatures as low as 1200°F. Agglomeration of the phase took place with prolonged heating at 1200°F or reheating to higher temperatures. Solution of χ phase in heat CM 68 became evident after 5 hr heating at 1800°F, solution being practically complete at 2200°F. In the case of heat CT 60, solution of χ phase occurred after 2 hr heating at 2000°F, the more stable χ phase being of higher molybdenum content.

Concentrated Murakami's solution (30 g K₃Fe(CN)₆ and 30 g KOH in 60 cc of water) failed to stain χ phase in heats CM 68 and CT 60, although it had been reported to be effective in staining σ phase in 19-9-W-Mo steel.³

As the CT 60 alloy was heated from 1200° to 2200°F the lattice parameter of the χ phase increased from 8.89 to 8.92Å.

Modified Type 446 Stainless Steel: Fig. 3 shows the microstructures of heat A-748, a type 446 stainless steel modified by the addition of molybdenum and tungsten. The specimen was heat-treated for ½ hr at 2000°F plus 40 hr at 1600°F. The diffraction pattern of the extracted residue showed strong lines of χ and some weak lines of σ .

According to Andrews,² the least amount of molybdenum for the appearance of χ phase in Cr-Ni-Fe alloys was about 3 pct. The fact that heat A-748 contained 1.62 pct Mo and 0.91 pct W leads to the conclusion that tungsten and molybdenum act similarly in promoting χ formation. This conclusion is supported by the presence of χ phase in extracted residues from heats F-178 (25 pct Cr, 10 pct Mo, balance Fe) and F-181 (25 pct Cr, 5 pct Mo, 10 pct

W, balance Fe). Microstructures of these samples are shown in Figs. 4 and 5.

Type 316, Type 316L, and Type 317 Stainless Steels: Commercial heats of types 316, 316L, and 317 stainless steels were chosen at random from mill production. Tables III and IV show the diffraction data on anodic extracts from specimens of the heats in various conditions as-received and heat-treated.

From the compiled experimental data the following deductions seem to be logical: 1—Cold working accelerates σ formation. 2—Cold working suppresses χ formation. 3—The maximum temperature for stable σ phase is under 1800°F for type 316 steel or under 2000°F for type 317 steel. 4— χ phase forms from solution-treated steels at the temperature range of 1400° to 1800°F. The rate of χ formation seems to reach the maximum around 1600°F. χ phase disappears after heating type 316 steel for 50 hr at 1800°F or after heating type 317 steel to 2000°F.

Comparing diffraction patterns on extracts from type 317 steel with those from type 316 (Tables III and IV), it appears that increasing molybdenum content promotes stability of both χ and σ phases.

Figs. 6 and 7 show respectively the microstructure of σ and χ phases in the austenitic matrix of type 317 stainless steel. Although no reagent has been found to differentially stain σ and χ phases, the differences in characteristic microstructures shown in Figs. 6 and 7 permit some degree of distinction, since χ phase tends to form along preferential atomic planes of the matrix of the annealed material, whereas a general precipitation of σ phase was observed in the cold-worked material.

Experimental Nickel-Base Alloy: Fig. 8 shows the as-cast microstructure of 25 pct Cr-10 pct Mo-Ni alloy which contains a very slight amount of an extraneous phase. The X-ray diffraction pattern of the solid specimen showed no trace of χ phase. No residue was recovered after the as-cast alloy was subjected to anodic FeCl₃ extraction.

It is therefore evident that there is no corresponding χ phase in the nickel-base Cr-Mo alloy.

Experimental Cobalt-Base Alloy: Fig. 9 shows the microstructure of an as-cast 25 pct Cr-10 pct Mo-Co alloy. No residue was recovered from the anodic FeCl₃ extraction of the alloy. Diffraction pattern on the solid specimen showed only face-centered cubic β and hexagonal close-packed α cobalt phases.

Observed Properties

Chemical Analysis: The chemical analyses in Table V on isolated phases indicate that χ phase is essentially an intermetallic compound of chromium, molybdenum, and iron. In this tabulation the total weight percentage of reported elements is so close to 100 pct that the analyses reported represent those of the isolated phases.

Table V. Chemical Analyses on Isolated Phases

* The specimen was anodic FeCl₃ extract from CT 60 cast alloy and the crystal structure was body-centered cubic, $a = 8.89\text{\AA}$.
† vs, very strong; s, strong; ms, medium strong; m, medium; w, weak; mw, medium weak; vw, very weak.
‡ Calculated according to body-centered cubic, $a = 8.888\text{\AA}$.

Molybdenum tends to concentrate in both χ and σ phases of Cr-Mo-Fe and Cr-Ni-Mo-Fe alloys. There are significant amounts of nickel in both χ and σ phases in type 317 steel. No significance was attached to the reported carbon content because of possible carbon pick up with the technique employed.

It is significant that the χ phase has practically the same chemical composition as the σ phase in type 317 stainless steel.

Crystal Structure: Table VI shows the X-ray diffraction data on χ phase isolated electrolytically in FeCl₃ solution from as-cast CT 60 alloy. The lattice parameter of χ phase isolated from all the alloys studied showed variation from 8.89 to 8.92Å.

The observed similarity in composition between χ and σ phases in type 317 stainless steel leads to some speculation as whether χ may be an ordered structure of σ which is known to be of a distorted body-centered cubic structure.

Microhardness: Table VII shows the microhardness of χ phase formed under various conditions of heat treatment.

Summary

1— χ phase was found in as-cast 23 pct Cr-10 pct Mo-Fe alloy as well as in heat-treated 316, 316L, 317, and modified 446 stainless steels.

2— χ phase resembles σ phase in its metastability, chemical composition, and brittleness.

3—There is no corresponding χ phase in either nickel or cobalt-base Cr-Mo alloy.

4—In stainless steels of the 316 and 317 types, cold working appears to promote σ but suppress χ formation. For applications involving extended time at elevated temperatures, the formation of χ or σ phase appears to depend upon whether the previous history involved solution treatment or cold work. In welded sections, riveted joints, or other strained areas of a large vessel where solution treatment is not possible, σ formation will be unavoidable, possibly without even partial χ formation.

Acknowledgments

The author wishes to acknowledge the assistance of staff members of the Allegheny Ludlum Research Laboratories in various phases of this work. J. A. Berger of the University of Pittsburgh furnished samples of some of the experimental alloys and Laurence C. Hicks, Director of Research, Allegheny Ludlum Steel Corp., has given very helpful suggestions.

Effect of Small Additions of Oxygen on Lattice Constants And Hardness of Zirconium

by R. M. Treco

The effect of small additions of oxygen on the hardness, density, and lattice parameters of high purity zirconium has been investigated. Precision parameter values and density of oxygen-free zirconium are given as: $a_0 = 3.2258$ kX units, $c_0 = 5.1373$ kX units, $\rho_{25} = 6.507$ g per cc.

THE effect of oxygen on the hexagonal-phase lattice constants of pure zirconium is of interest for several reasons. The extensive hardening effect of oxygen noted by previous investigators¹ must be due in part to the lattice distortion accompanying its introduction and possibly to the preferred position of the oxygen atoms. De Boer and Fast² have shown that oxygen is taken into solid solution in large amounts, appearing to occupy an interstitial position. These authors also found that expansion of the lattice was not uniform since the a axis attained a constant value after the addition of 10 atomic pct while the c axis continued to expand. It was thought in the present work that this expansion of the zirconium lattice with increasing amounts of oxygen

should lend itself to the determination of oxygen in the metal in the absence of other impurities. Also present-day production of iodide metal has resulted in much higher purity, so that a new check on the lattice constants of unadulterated zirconium appeared desirable.

Zirconium has been found to differ in some properties, particularly hardness and density, depending on the specific refining process employed. Some data on metal prepared by different methods are included here.

Experimental Procedure

A series of oxygen alloys of increasing gas content were prepared from very pure, degassed crystal bars in a high vacuum glass system of special design as described elsewhere.³ The alloys thus prepared were cold-rolled into strip and thoroughly annealed to produce a fine-grained recrystallized structure with a minimum of residual strains. Fig. 1 illustrates a typical microstructure in which the absence of inclusions is indicative of metal purity. Samples were electropolished and etched heavily, then placed in a back-reflection focusing camera of 5 in. diam in such a way as to allow continuous rotation during a run. Cobalt radiation was used for the exposures and exposure times varied from 3 to 6 hr on single-emulsion film. Temperature measurements were taken during each run to establish room temperature corrections.

Parameter Calculations

The films thus obtained usually consisted of 10 α doublets which were measured three times and averaged. Typical data obtained from a single film are assembled in Table I along with the calculated maximum reading error for each line.

Calculation of the lattice constants for each sample was carried through by Cohen's method⁴ with error determinations as outlined by Jette and Foote.⁵ This method results in a least squares solution of the lattice constants and in the present case was modified to include a correction for systematic errors, the equations being set up to avoid the loss of significant figures in subtraction. The notation for the equations employed should be clear from ref. 5, these equations being:

$$\Delta A \Sigma \alpha_i^2 + \Delta C \Sigma \alpha_i \gamma_i + \Delta D \Sigma \alpha_i \delta_i = \Sigma \alpha_i v_i \quad [1]$$

$$\Delta A \Sigma \alpha_i \gamma_i + \Delta C \Sigma \gamma_i^2 + \Delta D \Sigma \gamma_i \delta_i = \Sigma \gamma_i v_i \quad [2]$$

$$\Delta A \Sigma \alpha_i \delta_i + \Delta C \Sigma \gamma_i \delta_i + \Delta D \Sigma \delta_i^2 = \Sigma \delta_i v_i \quad [3]$$

($i = 1, 2, 3 \dots n$)

Table II. Analysis of Zirconium Sample Z62-1A

Element	Weight Percentage	Atomic Percentage
Carbon	0.0640	0.484
Oxygen	0.0260	0.147
Nitrogen	0.0010	—
Iron	0.0280	0.0455
Hafnium	0.0280	0.0142
Aluminum	0.0030	—
Calcium	0.0012	—
Chromium	0.0015	—
Copper	0.0010	—
Magnesium	0.0008	—
Manganese	<0.0005	—
Nickel	<0.0050	—
Lead	<0.0020	—
Silicon	0.0040	—
Tin	<0.0020	—
Titanium	0.0045	—
Vanadium	<0.0100	—

In this particular case of varying composition the difference terms (ΔA , ΔC , etc.) change progressively with the addition of oxygen.

The calculated lattice constants were plotted against oxygen concentration, and with the assumption of linear relations, a least squares equation was obtained for each parameter as a function of oxygen content. All lattice parameter values were corrected to a temperature of 25°C using the data of Russell⁶ for pure zirconium.

Zirconium Analysis

Zirconium used for the oxygen series consisted of five crystal bars from one selected lot, all of which were found to be of similar analysis. Table II gives the complete analysis of the control sample. The only substantial impurities found were carbon and oxygen of which the former was neglected in the

Fig. 1—Zr-O alloy cold-reduced 5.6 pct and annealed to produce fine-grained structure. Polarized light. X100. Area reduced approximately 50 pct for reproduction.

lattice parameter calculations since carbon concentration varied only slightly and its quantitative effect on lattice parameter was not known.

Determination of oxygen in very small amounts in zirconium is most successful with the hydrogen chloride method.⁷ Initial oxygen content of the bars before controlled oxygen additions was most difficult to obtain since it was small and varied slightly from sample to sample. In order to determine this initial oxygen, it was necessary to analyze several samples from a given bar. Since the amount of oxygen added to each sample was known accurately by two other independent checks, namely, weight gain and gas volume, these values could be plotted against the values obtained from chemical analysis, producing a linear plot. The curve obtained was easily shifted to correct each individual analysis for initial oxygen. This method minimized, but did not eliminate, the uncertainties in total oxygen content of each sample.

The atomic percentage of oxygen for each alloy of the series was calculated on the basis of oxygen and zirconium only. The first value listed in Table III was based on the known addition of oxygen, while the second value was corrected for initial oxygen. The correction is shown to be small in most cases, the corrected value being used for discussion purposes.

Results and Discussion

The calculated values of the zirconium hexagonal close-packed lattice constants are given in Table III together with the corresponding oxygen content. A plot of a and c axes as a function of the atomic percentage of oxygen is shown in Fig. 2, while Fig. 3 shows a corresponding plot of axial ratio and unit cell volume. These plots indicate a linear expansion of the lattice with increasing oxygen content as is usually found in dilute primary solid solution alloys. Within the range investigated there is no apparent effect on the axial ratio which remained constant.

The best value of the lattice constants for the

Fig. 2—Zirconium lattice parameter change with oxygen.

initial high purity crystal bar of the composition given in Table II is as follows:

$$a_0 = 3.2256_2 \pm 0.00014 \text{ kX units}$$

$$c_0 = 5.1370_0 \pm 0.00036 \text{ kX units}$$

$$c/a = 1.5926$$

An extrapolation of the two lattice parameter curves was achieved by a least squares solution of the lattice parameter-percentage of oxygen data with the resulting equations:

$$a_0 = 3.22580 + 0.0010184 \times (\text{atomic percentage of oxygen}) \text{ Standard deviation} = \pm 0.00095$$

$$c_0 = 5.13732 + 0.0019967 \times (\text{atomic percentage of oxygen}) \text{ Standard deviation} = \pm 0.00156$$

Lattice parameters for oxygen-free zirconium obtained from these equations together with their probable errors are as follows:

$$a_0 = 3.2258_0 \pm 0.00064 \text{ kX units}$$

$$c_0 = 5.1373_2 \pm 0.00105 \text{ kX units}$$

$$c/a = 1.5926$$

The standard deviations of the two parameter equations proved disappointingly large. Despite the precision of individual parameter calculations, the equations for oxygen concentration did not prove sufficiently accurate to justify their use in chemical analysis. It will be noted that the parameter values for samples 2C and 2B appear to be lower than expected, and if these data are neglected, the remain-

ing parameter values result in a good linear relation. However, exhaustive checks on all the data failed to show any statistical or other justification for discarding the results from these samples. In addition, the hardness of these samples was consistent with other hardness data, see Fig. 4.

Comparison of these data for zirconium with a similar study on titanium by Clark⁸ is of interest because of the similarity of the two metals. In his work, Clark showed that the a_0 parameter remained relatively constant while the c_0 parameter, hence the c/a axial ratio, increased linearly with oxygen concentration. This is at variance with the present results for zirconium and somewhat surprising since the smaller unit cell of titanium would be expected to expand to a much greater extent than zirconium. Lattice strains ($\Delta V/V_0$) calculated from the respective data for 0.35 wt pct oxygen are 0.128 pct for titanium and 0.200 pct for zirconium.

Hardness: Oxygen dissolved in zirconium produces a large increase in hardness. This is shown in Fig. 4 in which average hardness values of oxygen alloys from the original five bars are plotted against oxygen content, and the X-ray samples are seen to be consistent with the curve.

Although zirconium dissolves as much as 40 atomic pct of oxygen,² the presence of as little as 2.0 atomic pct embrittles the metal to such an extent that cold working and machining are impossible. Some success has been achieved with grinding, though the elimination of chipping is difficult. The remarkable decrease in ductility with such small additions suggests that the first oxygen atoms occupy preferred positions in the lattice thus interfering with the normal slip processes. In addition, it was also observed in this work that oxygen alloys show little tendency to form mechanical twins, in marked contrast to pure zirconium.

In view of these observations, it is of interest to

Fig. 3—Zirconium lattice change with oxygen.

consider the recent work of Rosi et al.,⁹ which appears to show that slip and twinning in α titanium do not occur in the usual hexagonal basal plane, but instead slip occurs in the $\{10\bar{1}0\}$ and $\{10\bar{1}1\}$ planes and the direction $\langle 11\bar{2}0 \rangle$; while twinning occurs in the planes $\{10\bar{1}2\}$ and $\{11\bar{2}2\}$.

Since titanium and zirconium have similar axial ratios ($\text{Ti} = 1.587$, $\text{Zr} = 1.592$), exhibiting marked

similarities in their deformation patterns, it appears likely that the titanium mechanism may also apply to zirconium. While these novel slip and twinning systems allow greater ductility in plastic deformation than basal slip, it is also apparent that the presence of interstitial solute atoms are more likely to interfere with prismatic or pyramidal slip. Considered in this light the observed decrease in ductility and lack of twinning in Zr-O alloys are not surprising, although solute size is but one of the factors affecting mechanical properties.

The hardness of zirconium has also been found to vary with the refining process and this has been attributed to variations in residual constituents.

Fig. 4—Zirconium hardness change with oxygen.

Metal produced by magnesium reduction is considerably harder than iodide crystal bar despite extensive efforts to improve purity. These improvements have resulted in metal substantially free of metallic impurities. Removal of the last traces of the three elements, hafnium, carbon, and oxygen, has not been possible by metallurgical methods. Residual hafnium does not appear to be responsible for the gross hardening effect since it also occurs in similar concentration in soft crystal bar and is nearly identical to zirconium in lattice constants and atomic diameter. Carbon, oxygen, and to a lesser extent nitrogen remain as the principal hardening agents. Since all three elements normally form interstitial solid solutions, the hardening effect is apparently caused by strain in the crystal lattice.

In order to examine this hardening effect, the strain induced in the crystal lattice by increasing amounts of oxygen has been calculated from the

unit cell volume of each of the X-ray samples as shown in Table III. Since oxygen content was the only significant variable in this series (carbon and nitrogen being relatively constant), a direct correlation between hardness and lattice strain should be apparent. Fig. 5 shows a plot of these data in which a reasonably good linear correlation was obtained for the amount of data available.

Density and Composition: Scattered density values given for zirconium in the literature are not entirely consistent. This may be attributed to the presence of impurities, particularly hafnium, carbon, and

Fig. 5—Zirconium hardness relation to lattice strain.

oxygen, in unknown amounts, which produce significant density differences. A precise calculation of X-ray density requires not only correct parameter measurement and quantitative chemical analysis, but also, in the case of metals, the characteristic dis-

persion of impurities, e.g., substitutional or interstitial atoms in solid solutions. Densities in the present work have been calculated from atomic percentages according to the relation

$$\rho = \frac{2(\Sigma A_s + \Sigma A_i)}{NV}$$

where: ρ is the density in g per cc; ΣA_s , the sum of substitutional atomic weights; ΣA_i , the sum of interstitial atomic weights; N , Avogadro's number; and V , the unit cell volume.

Density values determined as above are shown in Table IV for increasing oxygen content. Based on the extrapolation of unit cell volume, see Fig. 3, and interstitial solution of carbon and oxygen, the best density value for oxygen-free, low hafnium crystal bar is 6.507 g per cc. Increased oxygen caused an increase in density despite the observed linear increase in unit cell volume. Comparison of these data with similar work of de Boer and Fast also included in Table IV shows that the present values are significantly lower than previously found, the previous data also showing a decided density increase with added oxygen. The observed difference in absolute density is satisfactorily explained by the much lower hafnium content of the present metal (0.014 vs 0.50 atomic pct O). In addition, the relative change in density per atomic percentage of oxygen is in good agreement with the previous work.

The effect of composition on density and lattice constants of four selected types of zirconium is shown in the data of Table V in order of decreasing purity. The separation of hafnium to produce low hafnium metal results in lower density and higher zirconium assay. Low hafnium iodide crystal bar had the highest purity with a zirconium content of 99.325 atomic pct. Magnesium-reduced sponge purified by vacuum melting with separation of hafnium was also found to be of very high purity.

Observed agreement between calculated corrected densities and measured densities is consistent with the initial assumptions of interstitial solution of oxygen atoms and substitutional solution of hafnium atoms. The necessity of including minor elements in the density calculations whenever true values are desired is shown by the lack of agreement between uncorrected and measured densities included for comparison in Table V. The spread of density values obtained in this work explains the previous lack of consistent results in the literature, since minor impurities may cause the density to vary from about 6.45 to 6.65 g per cc.

Summary

A series of oxygen alloys of high purity zirconium crystal bar examined by X-ray diffraction showed a marked expansion of the hexagonal lattice with increasing oxygen. Precision lattice constants of this zirconium (analysis of Table II) were as follows: $a_0 = 3.22562 \pm 0.00014$ kX units; $c_0 = 5.13709 \pm 0.00036$ kX units. Extrapolated lattice parameter values were also obtained for oxygen-free zirconium. Oxygen is shown to be an active hardening agent in zirconium, occupying an interstitial position in solid solution.

The effect of minor impurities on density was found to vary with the specific elements. X-ray density of oxygen-free, high purity crystal bar was found to be 6.507 g per cc.

A comparison of purity and density of various types of zirconium is included.

Acknowledgment

The author wishes to express his appreciation to A. R. Kaufmann for his enthusiastic support of this work, and to H. Sawyer for his part in preparing and measuring the diffraction data. This work was carried out at the Massachusetts Institute of Technology Metallurgical Project under Contract AT (30-1)-981 with the U. S. Atomic Energy Commission.

Development of Mechanical and Magnetic Hardness in a 10 Pct V-Co-Fe Alloy

by Richard W. Fountain and Joseph F. Libsch

CONSIDERABLE time and effort have been expended recently in research designed to provide a better understanding of the solid state transformations leading to the permanent magnet qualities of many commercial alloys. The knowledge derived from these investigations has resulted in the development of new magnetic materials as well as improvements in some of the older materials. The permanent magnet qualities of the newer alloys having high residual inductions and high coercive force values, have been attributed to the precipitation of a second phase or an order-disorder transformation in a solid solution.

The ternary Co-Fe-V alloys provide an interesting group of magnetic materials having a wide range of magnetic properties. The low vanadium alloys¹ possess soft magnetic properties similar to the binary Co-Fe alloys, while at higher vanadium contents (about 10 pct) interesting permanent magnet properties are obtained.^{2,3} Previous work by Nesbitt⁴ on the ternary Co-Fe-V permanent magnet materials, resulted in the conclusion that the precipitation of a second phase, γ , was responsible for the permanent magnet qualities of these alloys. However, unlike the conventional precipitation hardening alloys, the γ phase, which is stable at high temperatures, is precipitated in the low temperature α phase upon aging. Recent work by Geisler and Martin^{5,6} has established that the order-disorder reaction inherent in the binary Co-Fe alloys is also present in the ternary Co-Fe-V alloys. On the basis of their investigation, it was proposed that ordering of the α phase is also a possible explanation of the mechanical and magnetic hardening in these alloys. Thus, it appears that the Co-Fe-V alloys are rather unique in that two solid state transformations are taking place which may account for the properties of these alloys.

R. W. FOUNTAIN, formerly Graduate Student, Lehigh University, is now associated with the Research Laboratories, Union Carbide and Carbon Corp., Niagara Falls, N. Y., and J. F. LIBSCH, Member AIME, is Associate Professor of Metallurgy, Lehigh University, Bethlehem, Pa., and Director of the Magnetism Project sponsored by the Signal Corps Engineering Laboratories, Fort Monmouth, N. J.

Discussion on this paper, TP 3404E, may be sent, 2 copies, to AIME by March 1, 1953. Manuscript, April 9, 1952; revised, Sept. 22, 1952. Philadelphia Meeting, October 1952.

In view of these facts, the present investigation was undertaken to study the mechanism of mechanical and magnetic hardening in the 10 pct V-Co-Fe alloy with particular reference to the role of the γ phase; and to correlate the results of this study with other magnetic properties. In addition, the influence of increasing vanadium contents on the transformation of Co-Fe alloys was also undertaken to supplement the main objective of the investigation.

Experimental Procedure

The Co-Fe-V alloys used for study consisted of: 1—a commercial lot of Vicalloy I, a 10 pct V alloy, and 2—alloys prepared by powder metallurgy and containing 52 pct Co and 0 to 14 pct V, balance iron. The commercial alloy was received in the cast and forged condition and was used primarily for the detailed study of hardness, electrical resistivity, and magnetic properties of the 10 pct V alloy.

The powder metallurgy alloys were prepared from electrolytic iron, commercial cobalt, and ferrovanadium powders. The processing cycle was as follows:

1—Elemental powders were weighed and mechanically mixed for 24 hr.

2—Mixed powders were pressed at 60,000 psi into the form of bars $\frac{5}{8} \times \frac{5}{8} \times 5$ in.

3—Bars were sintered in an atmosphere of purified dry hydrogen for 24 hr at temperatures ranging from 1380° to 1340°C, depending upon the vanadium content. The as-sintered bars were cut in half; and one half was machined to $\frac{7}{16}$ in. diam for thermal analysis. The remainder of the bar was hot forged to approximately 0.050 in. for X-ray diffraction analysis.

Additional details of sample preparation are presented subsequently according to the type of test performed.

Thermal Analysis Measurements

One of the simplest and most widely used tools for determining phase relations as they change with temperature and composition is to study the rate of change of temperature of a material as heat is supplied or extracted at a constant rate. The thermal analysis method used in this investigation is the inverse-rate method described by Smith.⁷

The specimens for thermal analysis were solution treated at 1100°C for 1 hr followed by oil and liquid nitrogen quenching. The liquid nitrogen quench was used in an effort to transform any retained γ phase, thus providing a single-phase alloy at the start of the analysis.

Fig. 1a is the thermal analysis curve obtained upon heating an alloy containing 52 pct Co, 46 pct Fe, and 2 pct V. The discontinuities in the curve at the critical temperature of order and at the α - γ transformation temperature are clearly shown in this example.

Thermal analysis curves similar to that of Fig. 1a were obtained for alloys containing less than 6 pct V. In alloys containing 6 pct or more vanadium a curve similar to that of Fig. 1c was obtained. The striking difference between these two curves is at once observed as an additional peak lying between the critical temperature of order and the α - γ transformation temperature of the 2 pct V alloy. This additional peak is present in all the curves for specimens ranging from 6 to 12 pct V. This peak is interpreted as the beginning of the α - γ transformation, while the second peak at 888°C has been interpreted as the completion of the α - γ phase transformation. However, recent preliminary X-ray diffraction tests with chromium radiation indicate the possible presence of a hexagonal phase in aged samples. If substantiated by additional work, this may serve as an alternative explanation for the additional peak in the thermal analysis curves.

Another significant feature of these curves is the continued decrease in intensity of the ordering peak as the vanadium content is increased. Although no quantitative relation can be obtained from these curves, there are two qualitative implications. First, the increased vanadium content may directly prevent the formation of the ordered structure by blocking diffusion processes, or second, it may enter into a second phase with the iron and cobalt and thus may change the ratio of Fe-Co necessary to form the ordered structure. The second possibility seems to be more likely as the continued additions of vanadium lower the α - γ transformation indicating that the vanadium is promoting the formation of the γ phase. At 14 pct V the alloy shows a very small transformation peak indicating that very small amounts of the α phase are present.

X-Ray Diffraction Analysis

X-ray diffraction analysis was used principally to determine the phase relations of Co-Fe-V alloys heat-treated to produce nonequilibrium conditions, in the hope that the results would provide more information regarding the actual mechanism of mechanical and magnetic hardening.

The diffraction studies were carried out using a General Electric XRD-3 X-ray diffraction apparatus for direct measurement of diffracted intensities. The results obtained by this method were checked in many cases by the use of conventional film techniques.

As was mentioned earlier, the as-sintered bars were forged to 0.050 in. for X-ray diffraction analyses. The samples were solution treated individually by placing them in a stainless steel tube and providing a purified dry hydrogen atmosphere. The specimens were held for 1 hr at 1100°C and quenched in oil. When the sample had reached room temperature the atmosphere was discontinued and the sample was removed from the tube and

quenched in liquid nitrogen. Aging was carried out in lead and the specimens were water quenched from the aging temperature. Filtered cobalt radiation was used in this investigation.

In the early stages of the diffraction study, it was found that due to the sluggishness of γ - α transformation in the higher vanadium alloys, many samples would appear to be entirely α phase, but when etched to remove the surface layers, traces of γ phase were detected. For this reason, all subsequent samples were etched until no change in the diffraction pattern occurred.

The results of the X-ray diffraction study are reported in Table I. Two main conclusions can be drawn from these data. First, a face-centered cubic γ phase can be precipitated from the body-centered cubic α phase at temperatures as low, in the higher vanadium alloys, as 400°C. Second, ordering in the

α phase can take place in the temperature range of 600° to 700°C. This fact was also established by the thermal analysis data. However, the detection of the ordered phase was very difficult and for this reason any change in lattice parameter due to ordering could not be determined.

Table II presents data for the amounts of the α and γ phase present with various vanadium contents and aging temperatures. From this table it can be seen that the additions of vanadium up to 10 pct to the Co-Fe alloys cause a gradual increase in the lattice constant of the α phase in both the as-quenched alloys and those aged at 400°C. This increase is observed to take place until the γ phase begins to precipitate at which point the lattice constant tends to decrease. This increase of the lattice constant would, of course, be expected, but the decrease of the constant due to the precipitation of γ suggests that the vanadium is going primarily into the γ phase. In addition to the change of the lattice constant due to γ precipitation, additional broadening of the peaks on the diffraction patterns occurred indicating that considerable strain was being introduced into the system due to the γ precipitate. This broadening was observed to take place even before the γ phase could be detected. Although no such trend in the lattice constants was observed at the 600°C aging temperature, additional broadening of the diffraction peaks was observed. The presence of more γ phase in the 12 pct V alloys as-quenched than when aged at 400°C is probably due to the sluggishness of the γ - α transformation on quenching. When the specimen was aged at 400°C, the retained γ phase was unstable at this temperature and consequently transformed to the α phase. This process is very familiar in the case of tempering alloy steels which contain retained austenite after quenching.

Mechanical and Magnetic Hardening in 10 Pct V-Co-Fe

From the results presented thus far, it has been established that suitable heat treatments can cause the precipitation of a γ phase as well as ordering in the α phase. However, the ordering reaction is confined mainly to the temperature range of 600° to 700°C for practical heat treatments which develop best magnetic properties. Thus, it seems that two mechanisms are available to explain the hardening

characteristics and permanent magnet qualities of the 10 pct V-Co-Fe alloy. The precipitation of the γ phase is certainly a possible explanation, as many binary⁸ and ternary⁹ permanent magnet alloys develop their properties by this process. On the other hand, however, an order-disorder reaction is responsible for the permanent magnet qualities of the well-known Co-Pt alloys.¹⁰ Thus, the problem presented is to separate the effects of these two reactions.

Hardness and Electrical Resistivity Measurements

In an effort to provide an answer to the problem just referred to, an extensive survey of electrical resistivity and mechanical hardness was made on a commercial Co-Fe-V alloy of the Vicalloy I composition. The analysis of the alloy used for this purpose was as follows: C, 0.034 pct; Mn, 0.60; P, 0.014; S, 0.005; Si, 0.32; Co, 52.06; V, 9.10; and balance Fe.

The material for resistivity measurements was received in the form of hot rolled strip 0.055x $\frac{5}{8}$ x5 in. The resistivity samples were solution treated at 1100°C for 1 hr, first quenched in oil and subsequently into liquid nitrogen. The samples were aged in lead or salt at temperatures ranging from 300° to 800°C for varying time periods and water quenched from the aging temperature. The resistivity measurements were made using the well-known voltmeter-ammeter technique. The technique was checked thoroughly against known standards and a Kelvin double bridge and found to be capable of producing results accurate to within 1 pct.

The hardness measurements were made on $\frac{3}{8}$ in. sq samples cut from a $\frac{3}{4}$ in. hot forged bar of the same heat. Hardness samples were heat-treated in the same manner as resistivity samples.

The results of the electrical resistivity and hardness measurements are presented in Figs. 2 and 3. These data in conjunction with the X-ray diffraction data permit the drawing of some very interesting conclusions. The most striking feature of the resistivity curves is the sudden increase at aging temperatures below 600°C. This occurrence has been observed in the early stages of both precipitation hardening and ordering systems. As time is increased at temperatures below 600°C, the resistivity begins to decrease, although the hardness

Fig. 3—Influence of aging time and temperature upon the mechanical hardness of Vicalloy I.

is still increasing. These results are not contradictory as a change in electrical resistivity can be caused by slight variations in structure, whereas a macroproperty such as hardness is less subject to slight structural changes. The rapid decrease in the resistivity curves at temperatures of 600° to 800°C may be determined by two phenomena: 1—the coalescence of the γ precipitate, and 2—the effect of ordering in the α phase. As the temperature is increased to 800°C, a sudden reversal is observed in the resistivity curve. This result is most probably caused by the large amounts of γ phase present and disordering in the α phase.

The hardness curves of Fig. 3 are very revealing and need little explanation. The sudden rise in hardness at temperatures up to 600°C is almost certainly due to the precipitation of the γ phase, as at these low temperatures and short times the formation of the ordered phase was not detectable by X-ray diffraction or thermal analysis. Extremely long time periods at these low temperatures are also reported by Geisler and Martin⁶ before the ordered phase could be detected by diffraction analysis.

These time periods are much longer than those required to produce a substantial increase in hardness.

The characteristic shape of the curves of 300°, 400°, 500°C, and to some extent 550°C, suggests the existence of two stages in the precipitation process. The hump of the hardness curves is also observed in many of the common precipitation hardening systems such as Al-Cu. On increasing the aging temperature from 600° to 800°C, the maximum hardness is attained much more rapidly as would be expected, but the hardness decreases after very short time periods, indicating that overaging is taking place very rapidly.

The change in microstructure of this alloy on aging at 600°C for increasing time periods is shown in Fig. 4a to d. The metallographic samples were heat-treated according to the same cycle used in the hardness tests, except that they were subzero cooled in liquid oxygen rather than liquid nitrogen during quenching. All samples were water quenched from the aging temperature. The structure of Fig. 4a is for a sample in the as-quenched condition. According to X-ray diffraction analysis, this sample is all

Fig. 5—Magnetic properties vs vanadium content.

α phase. The slightly gray areas may be due to a difference in orientation on etching. After 8 hr at 600°C, Fig. 4b, grain boundary precipitation can be observed. On increased times, Fig. 4c and d, the precipitating phase seems to have completely enveloped the grains and has become quite massive. From Fig. 4d, the general intragranular precipitation can be seen. This sample is completely over-aged. Thus, from this series of micrographs, the course of precipitation of the γ phase can be observed.

Magnetic Properties

The influence of increasing vanadium content upon the magnetic properties of the 52 pct Co-Fe alloy prepared by powder metallurgy was determined. These tests were restricted to a single aging temperature of 600°C and an aging time of 2 hr. However, an extensive survey was also made on the influence of aging time and temperature upon the cast Vicalloy I alloy which was used previously in this investigation.

Experimental Procedure: The vanadium series of alloys was prepared using the same processing cycle

as that outlined for the thermal analysis samples. In addition, however, the magnetic test samples were hot forged to approximately 0.400 in. sq. Subsequently, the samples were solution treated at 1100°C for 1 hr and quenched in oil and liquid nitrogen. In all cases, the samples were aged in lead at 600°C for 2 hr and air cooled from the aging temperature. It should also be mentioned that after forging, the density of the powder magnets was 98 pct of the density of the cast material, and that the magnetic properties were very similar.

The Vicalloy I material was received in the form of hot forged bars $\frac{3}{4}$ in. sq. Test samples $\frac{1}{2}$ in. sq were machined from the as-forged bar and solution treated in the same manner as the powder parts. The test samples were aged at temperatures from 400° to 800°C for various time periods. The magnetic properties were determined on a General Electric saturation permeameter. All saturation values reported are for $H = 2000$ gauss.

Effect of Composition: The influence of increasing vanadium content on the magnetic properties of the 52 pct Co-Fe alloy in the as-quenched and aged condition is presented in Fig. 5. Several interesting conclusions can be drawn from these data. In the as-quenched condition, the saturation induction and residual induction decrease with increasing vanadium content. The highest values of saturation and residual induction are observed in the lower vanadium alloys, where the composition is closest to that of the high saturation binary Fe-Co alloy. The coercive force increases slightly with the vanadium additions, and this result would be expected merely from a composition standpoint.

On aging at 600°C, however, a striking change in properties occurs. The coercive force increases rather slowly with increasing vanadium content to 6 pct V after which it increases very rapidly. The highest values of coercive force are obtained in alloys containing 52 pct Co, 36 to 38 pct Fe, and 10 to 12 pct V. As vanadium content increases, the saturation induction decreases more rapidly in the aged condition than in the quenched condition. This occurrence is to be expected as Nesbitt⁴ reports that the γ phase is nonmagnetic and it was shown in the X-ray diffraction study that the γ phase began to precipitate at about 4 pct V. The residual induction values do not follow the same trend after aging as they did in the as-quenched condition. This difference in the values of residual induction is probably associated with a structural change in the α phase that will be discussed in greater detail later.

Fig. 6—Influence of aging time and temperature upon the saturation induction of Vicalloy I.

Fig. 7—Influence of aging time and temperature upon the residual induction of Vicalloy I.

Magnetic Properties of 10 Pct V Alloy: The results of the more extensive survey of the magnetic properties of the Vicalloy I alloy are presented in Figs. 6 to 8.

The saturation induction values, Fig. 6, show a general decrease as a function of time and aging temperature. The highest values of saturation are obtained by aging at 400°C. This would be expected because at this low temperature the amount of the γ phase present would be a minimum.

The initial low value of saturation induction after aging at 800°C is probably caused by large quantities of γ phase precipitated even at these very short aging times. The sudden reversal of the saturation induction is very interesting and provides some information concerning the kinetics of the reaction taking place. It appears, for example, that the primary difference between the 600° and the 800°C curve is the amount of γ phase precipitated. At 800°C, as the γ phase precipitated agglomerates, it reaches a large enough size to become an equilibrium state and then transforms on cooling to α by a martensite-like reaction. In this connection, it may be noted in Fig. 1e that 800°C is very near the critical temperature for the 10 pct V alloy.

The data of Fig. 7 show the changes in residual induction on aging. The residual induction increases with aging time in the temperature range of 400° to 550°C. At 600°C the rapid rise and decrease of the residual induction is most probably due to the rapid precipitation of the γ phase. The influence of ordering in the α phase may be playing an important role in the residual induction value for the 600°C aging temperature and for the longer time periods at 500° and 550°C. The behavior of the residual induction on aging at 800°C is similar to that exhibited by the saturation induction.

The values of coercive force obtained on aging are shown in Fig. 8. The general increase in coercive force as the aging time and temperature are increased does not seem to correlate with the mechanical hardness values reported earlier. The behavior of mechanical and magnetic hardness is, however, understandable. A very small nucleus of precipitate should be enough to affect the mechanical hardness sufficiently since such a nucleus and the strained area about it will impede the motion of a dislocation, which is the cause of hardness. On the other hand, the effect on H_c may not be felt until the precipitate is much larger. It appears al-

Fig. 8—Influence of aging time and temperature upon the coercive force of Vicalloy I.

most as though there is some critical diameter to the precipitate which is why at 700°C, H_c begins to get smaller. Such an effect has been found by Dijkstra and Weert in the Fe-C system.¹¹ The most interesting point observed from these data is the increase in the coercive force at the longer times at 500° to 550°C, and, of course, the shorter time periods at 600°, 700°, and 800°C.

Correlation of Structure and Mechanical Hardness

The existence of a γ phase precipitate can be detected by X-ray diffraction analysis in samples aged at 400° to 600°C. At temperatures of 600°C, the first sign of the γ phase is detected at 4 pct V. At lower temperatures, 400°C, small quantities of the γ phase are detected at 10 pct V. The existence of the ordering in the α phase was found to take place in the temperature range of 600° to 700°C. By electrical resistivity and hardness measurements it has been established that the γ phase precipitate is responsible for the mechanical hardening of this alloy in samples aged in the temperature range up to 600°C. In some cases, the maximum hardness obtained is equal to that of fully hardened steel. Above 600°C it is difficult to distinguish between the contribution of the γ phase and ordering in the α on mechanical hardening. However, the very rapid increase in hardness at the short aging times at all the aging temperatures, seems to be more characteristic of an age hardening system. It is certainly possible that the ordering in the α phase is contributing to the mechanical hardening at 600°C and higher aging temperatures.

Concerning the magnetic properties, the influence of the formation of γ phase on the saturation values is quite clear. The presence of the γ phase results in a decrease in the saturation induction due to its nonmagnetic character. It is also possible that the precipitation of this phase may produce a composition change in the magnetic α phase, which detracts from its magnetic properties, thus aiding in the decrease in saturation induction.

The increase in residual induction with aging time and temperature is most probably due to γ phase precipitation and possibly ordering in the α phase at the higher temperatures. It would be expected that the precipitation of the nonmagnetic γ phase would result in a decrease in residual induction similar to the decrease observed in the saturation induction. However, it should be remembered that residual induction is a structure sensitive property. Therefore, it appears that the strain accompanying the γ phase precipitation is resulting in a more favorable domain structure, so that during magnetization a greater degree of domain orientation is obtained. At the higher aging temperature, 600°C, ordering in the α phase probably contributes to this mechanism, resulting in the very rapid initial increase in the residual induction. As the aging time at 600°C increases, the γ phase increases to a size where it loses its efficiency to orient the domain structure and merely acts to decrease the residual induction by its nonmagnetic character.

In regard to the high values of coercive force obtained on aging, the presence of the γ phase appears vital. The large coherency strains associated with the formation of the γ phase and its subsequent precipitation in the grain boundaries and along certain crystallographic planes would appear capable of producing a coercive force of the magnitude reported, i.e., 300 oersteds. In this connection it may

be noted that there is an appreciable difference in the lattice parameter of the α and γ phases.

On the other hand, the lattice constant of the Fe-Co ordered phase differs so slightly from that of the disordered phase, that it would hardly seem possible that this slight difference would cause sufficient disregistry to produce such a large change in coercive force.

Summary and Conclusions

The results of this investigation may be summarized as follows:

1—Increasing vanadium additions to Co-Fe alloys lower the $\gamma \rightarrow \alpha$ transformation, thus promoting the formation of the nonmagnetic γ phase. The vanadium additions also decrease the intensity of the ordering reaction as determined by thermal analysis.

2—Precipitation of the γ phase is primarily responsible for the mechanical hardening in this system. Above 600°C it is felt that ordering in the α phase may be contributing to the mechanical hardening.

3—Increasing vanadium additions to Co-Fe alloys lowers the saturation and residual induction and increases the coercive force. The highest values of coercive force were found in alloys containing 52 pct Co, 36 to 38 pct Fe, and 10 to 12 pct V.

4—The increase in residual induction of the Vicalloy I alloy on aging was attributed to the production of a more favorable domain structure accompanying the γ phase precipitation.

5—The high values of coercive force obtained for this alloy have been associated primarily with the formation and precipitation of the γ phase in the magnetic α phase.

Thermal and Dilatometric Investigation of the Alloys of Cobalt With Chromium and Molybdenum

by A. G. Metcalfe

Observations at temperature are used to investigate the phase changes in alloys containing more than 50 pct Co and above 1000°C. The nonsuppressible transformations in cobalt above 1120°C and in the intermetallic compound Co_2Cr_3 are studied. The liquidus and solidus surfaces are determined. Insufficient data is obtained to complete the constitution diagram.

A REVIEW of some of the earlier work on cobalt¹ and on the binary systems with chromium²⁻⁴ and with molybdenum,⁵ showed that one likely source of differences might be attributed to the presence of phases at high temperatures which could not be retained by quenching. Consequently, the decision was made that only methods of examination at temperature should be used in this work. The correctness of this decision was confirmed during the course of the work by the investigation of the martensitic nature of the transformation in cobalt⁶ and by the decomposition of the high temperature form of the phase Co_2Cr_3 on quenching.⁷

The use of high temperature methods, including dilatometry and thermal etching led to the postulation of the existence of a high temperature form of cobalt with a probable hexagonal close-packed structure, transforming from cubic cobalt over a range of temperature from 1119° to 1145°C.⁸ One of the important pieces of evidence for this transformation was that it was observed in alloys with chromium and molybdenum which were nonmagnetic at this temperature so that confusion with magnetostriction effects was impossible. These results were not reported in this earlier paper, so that the data given here supply further evidence for the existence of a second allotropic transformation in cobalt.

A. G. METCALFE is Research Metallurgist at Deloro Smelting and Refining Co., Deloro, Ont., Canada.

Discussion on this paper, TP 3401E, may be sent, 2 copies, to AIME by March 1, 1953. Manuscript, April 14, 1952. Philadelphia Meeting, October 1952.

This paper represents part of a thesis by A. G. Metcalfe submitted in partial requirements for the degree of Doctor of Philosophy to the University of Cambridge, December 1950.

High temperature observations are necessarily much slower in producing results than the examination of quenched specimens at room temperature by conventional means such as X-ray diffraction or microexamination. The investigation has only covered a limited part of the field, as a result, extending from the liquidus down to about 1050°C and from the cobalt corner up to 50 pct alloying elements.

The differences between the various reported diagrams for the constitution of the Co-Mo and Co-Cr systems have already been mentioned. The best available diagram in the first system is due to Sykes and Graff⁹ which is shown in Fig. 1. Fig. 2 shows the latest Co-Cr diagram due to Elsea, Westerman, and Manning.⁷ A comparison reveals that these are incompatible because of the disagreement with regard to the number of allotropes of cobalt. Elsea, Westerman and Manning took their liquidus and solidus curves from Wever and Haschimoto.² The temperature horizontal in the two-phase field beneath the eutectic was placed 35° to 39°C higher than in earlier work^{2,4} with a new interpretation of the nature of this transformation. This interpretation also required a peritectic horizontal at about 1470°C, which has been confirmed here for an alloy with 53 pct Cr.

No investigation had been made of the ternary system until after this work had been terminated, when a section at 1200°C was published.⁹ In this work a ternary compound was found by the X-ray diffraction examination of quenched alloys. This compound contained less than 50 pct Co, and was thus outside the field investigated here. However, some reactions were found dilatometrically which could not be fitted on the diagram and are now believed

Fig. 1—Co-Mo constitution diagram according to Sykes and Graff.⁶

Fig. 2—Co-Cr constitution diagram according to Elsea, Westerman, and Manning.⁷

to be connected with this compound. Although this compound was observed in alloys of lower purity, its existence has had to be considered.

Apparatus

Vacuum Furnace: A sectional view of the vacuum furnace is shown in Fig. 3. The furnace consisted of either a single or a double alumina tube wound with either molybdenum or tungsten wire. The alumina crucibles were 6 in. long and 1 in. diam, with an auxiliary heater consisting of about 20 turns of tungsten wire at the top to prevent bridging of the charge. The vacuum vessel tipped about the trunnions shown in Fig. 3 to cast the alloy into a wrought iron mold, which could be heated. Pumping was continuous by means of a 1½ in. diam pipe leading through one of these trunnions to a taper giving direct connection with an oil diffusion pump. This can be seen in Fig. 4. The pressure could be kept below 1 micron of mercury throughout the melting and casting of both nickel and cobalt up to the highest temperature reached, 1710°C, but tended to be somewhat higher for melts containing chromium.

The temperature of the melt was measured by a thermocouple which could be lowered into the crucible by an Archimedean screw inside the vacuum vessel. The furnace was tipped mechanically to obtain reproducible conditions, see Fig. 4. A small refractory tundish at the top of the mold reduced the initial chill.

Thermal Analysis—Solidus: Thermal analysis on cooling was made in the vacuum furnace, followed by rapid remelting, and casting (after stirring well), in order to minimize composition changes due to evaporation. After homogenization of these ingots, small samples were heated inside a block of the type shown in Fig. 5. The position of the platinum thermocouple is shown by the dotted outline of the sheath. A W-Mo-W thermocouple recorded the difference in temperature between this thermocouple and the specimen which was insulated by coarse alumina powder. The thermocouple junction was pressed into a slit cut in the specimen. This block was then heated

Table I. Composition of Alloys

Fig. 3—Section of vacuum casting furnace.

at a constant rate inside a tube through which hydrogen was flowing. Nickel, wrought iron, and stainless iron were used for these blocks.

Dilatometer: A section through the dilatometer is shown in Fig. 6. The outer concentric tube was evacuated to improve temperature uniformity in the inner tube and to prevent leakage of air into it. A short piece of metal bellows took up any differential expansion. The specimen was short and of large diameter to reduce internal thermal gradients and can be seen in the lower drawing. The details of the adjustment device and of the transmission through the metal bellows to the dial gage can be seen in the upper diagram. The temperature range in which readings were taken was 1000° to 1425°C , for which mullite was found to be satisfactory, although trouble was experienced with creep before suitable supports were designed to take the weights of the ends.

Fig. 4—General view of furnace.

Measurements were made in vacuo and argon, although the latter was preferred for ease of working. One defect was found to be that the contraction of the specimen was not followed smoothly. However, the hysteresis on cooling was considerably greater than on heating, in agreement with general experience,²⁰ so that no advantage was lost by neglecting the cooling curves.

Creep of the specimen was encountered in the initial experiments with nickel,²¹ but was overcome by careful adjustment of the pressure.

Preparation of Alloys

The alloys were vacuum melted and cast using metal of the composition given in Table I. The following elements were also absent from both the cobalt and the chromium: Mo, Pb, Bi, Sb, As, Ag,

Fig. 5—Block for thermal analysis on heating.

Al, Mn, Sn, Zn, W, Nb, Ta, V, and Ti. No analysis was made for oxygen, hydrogen, or nitrogen. The cobalt had been made electrolytically although the analysis is for a sample after casting. The molybdenum metal powder was not analyzed, but was better than 99.8 pct pure.

It was assumed that all of the metals contained a certain amount of oxygen, and in addition it seemed likely that hydrogen might be present in the chromium. Some preliminary experiments revealed that if the pressure in the system was used to follow the evolution of carbon monoxide, deoxidation by means of carbon could be made. If too little carbon was added the pressure rose when carbon monoxide began to be evolved, but soon fell back to a low value when the carbon was exhausted. On the other hand if too much carbon was added, the pressure remained high owing to the reaction with residual oxygen in the system. At near the critical amount the pressure fell back to the usual value, but rose slightly if the melt was stirred.* Under these pres-

* This method was suggested by E. A. G. Liddiard and A. H. Sully of Fulmer Research Institute, England.

ures and temperatures the product of the concentrations of oxygen and carbon must be extremely low, so that analyzed carbon figures of 0.01 and 0.02 pct must mean low oxygen contents. The carbon content was always analyzed when it was believed to be higher than usual, on the basis of the above tests, so that where no result is reported it is probably below 0.02 pct. The best results were obtained by additions of carbon on the basis that the chromium contained 0.45 pct and the molybdenum 0.15 pct oxygen, confirmed by examination of the ingots for inclusions. These inclusions were solely chromic oxide which had been as high as 0.10 pct before the deoxidation technique was used, but dropped to below 0.01 pct with a residual carbon content of 0.01 to 0.02 pct. It was felt that the "carbon boil" would carry away any hydrogen or nitrogen in the alloy. No chromium nitride was ever detected in any alloy.

The alloys were superheated 100° to 150°C and then stirred well by means of the lateral and vertical movement of the thermocouple sheath. Cooling curves were then made, but were only taken to a little below the liquidus in most cases in order to avoid segregation. The previous superheating made it possible to remelt and cast quickly so as to avoid

Fig. 6—Dilatometer.

Fig. 7—Extrapolation of dilatometer results to zero rate of heating.

composition changes. The mold was heated to a temperature between 300° and 400°C for casting.

Composition changes due to evaporation were not serious in most of the alloys. The nominal 55 pct Cr alloy had the highest melting point and the highest chromium content, but in spite of extending the cooling curve to below the solidus, the alloy analyzed 53.3 pct Cr against 54.8 pct actually added. Much of this composition change would have occurred from the chromium metal before alloying, so that the change between the thermal analysis and casting was probably under 0.5 pct. Once the alloys had melted down, the small area of the crucible tended to restrict evaporation.

Alloy 2020 (a nominal composition of 20 pct Cr and 20 pct Mo) was allowed to cool in the crucible instead of being cast. The analysis figure quoted in Table II is for a sample taken from the bottom of the ingot and reveals the extensive segregation which can result. On the other hand alloy 3010 which was cast in the normal way, contained 28.2 pct Cr and 11.7 pct Mo at the top, against 28.2 pct

Cr and 12.0 pct Mo at the bottom of the ingot. In other cases where analyses were made at the top and bottom of the cast ingots, similar agreement was obtained.

The ingots weighed about 50 g and were checked for soundness and inclusions by density determinations and microscopic examination. Very little porosity was found (chill-cast cobalt had a density of 8.87 g per cc). Cracking was noticed on many alloys containing much chromium, which was later found to be connected with the transformation in the compound Co_2Cr_3 , see Fig. 2.

The ingots were homogenized by 36 to 48 hr heating at 1300° to 1325°C in a "gettered" vacuum.

Thermal Analysis

Cooling Curves: The temperatures were measured by means of a thermocouple, but as experience was gained many changes were made which increased the accuracy of measurement. The work on the Co-Cr binary was regarded as confirmation of existing diagrams^{2,7} rather than exploratory, so that when it was found that the technique used was not completely satisfactory, only a portion of it was repeated because the data obtained agreed with the earlier results, within its limits of accuracy.

Table I gives these thermal analyses results in the first group. The temperatures were determined by means of a W-Mo thermocouple in alumina insulators and sheath of 6 mm OD. This had been annealed at 1700°C and calibrated in situ against a Pt vs Pt-13 pct Rh thermocouple up to 1400°C, supplemented by melting point determinations at the Ni-Cr eutectic at 1342°C¹² and at the melting points of nickel at 1453°C and of cobalt at 1493°C.¹³ Agreement was within 3°C by these two methods of calibration and

fell between the calibration curves of earlier workers.^{14, 15} The agreement between these calibration curves seemed to justify the use of this thermocouple for a series of Co-Cr alloys. After four alloys had been investigated, a second calibration at the melting point of cobalt was made, when it was found that the calibration had changed by 31°C. A similar rise in the electromotive force at the melting point of cobalt was found when another couple was used for two more of these alloys. Most of these thermal analyses were made in duplicate at rates of cooling between 1° and 5°C per min before the primary arrest, but it was found almost impossible to prevent much supercooling which reached a maximum of 57°C for pure cobalt. This could not easily be remedied because this thermocouple was fixed in the melt, an arrangement which also led to the production of ingots of uncertain composition. Subsequent papers^{16, 17} have reported consistent results with this thermocouple, but as it appeared to be necessary to stir the molten alloy, this couple was not investigated further.

The second series of thermal analyses was made with the Pt vs Pt-13 pct Rh thermocouple which could be lowered into the melt when desired. It was found¹⁸ that the calibration varied with time, being at the rate of 3°C per hr at the melting point of cobalt and so occasional checks were made at the melting point of pure nickel or cobalt. In addition to these, the thermocouple was calibrated before and after each thermal analysis at the melting point of silver under standard conditions in a separate furnace. The movement of the thermocouple sheath was sufficient to give adequate stirring and to discourage supercooling which was usually zero and

never more than 5°C. The rate of cooling at the primary arrest varied between 0.9° and 6.5°C per min, although it was usually between 3° and 6°C per min. The thermal analyses results obtained with this thermocouple are considered to have an accuracy of $\pm 3.5^\circ\text{C}$.

A separate investigation of the causes of the change in the calibration of the standard platinum thermocouple¹⁸ led to the use of the Pt-1 pct Rh vs Pt-13 pct Rh thermocouple. The rate of change of calibration of this thermocouple at the melting-point of cobalt was 0.35°C per hr against the 3°C per hr of the

standard couple. The thermoelectric power was greater than 12 microvolts per °C over the range in which it was used. During the course of eight thermal analyses, the electromotive force at the melting point of nickel was observed to fall from 14.085 to 14.061 microvolts or a change of a little under 2°C. This increased stability allowed slower rates of cooling to be used which were between 1.7° and 4°C per min. The results obtained with this thermocouple are given in the third group in Table II. The accuracy of these results is considered to be $\pm 1.5^\circ\text{C}$.

Heating Curves: The whole ingot was used for dilatometry so that the specimens could not be cut until this work had been completed. Some of the determinations were repeated once, or twice, and all of these results are included in Table II.

Dilatometry: The specimen was heated to 1000°C and allowed to anneal at this temperature for a period of several hours before heating curves were determined. The first heating curve was at a rapid rate and was extended to a temperature approaching the solidus. Any irregularities in this curve were then investigated at two or three slower rates of heating which were usually between 0.5° and 4°C per min. The temperature of the start and the finish of each transformation was then plotted against the heating rate and extrapolated by a smooth curve to zero rate of heating. Fig. 7 illustrates this method of extrapolation for alloy 3805. Both of the reactions are peritectoids, and it was found that this type of variation of the transformation temperature with the rate of heating was a characteristic of some peritectoid transformations. It was observed where the composition of the product of the reaction changed rapidly as the transformation temperature was approached. At fast rates of heating, this adjustment of the solubility was largely incomplete, but a reaction was possible when the unsaturated terminal

solid solution crossed into a two-phase field at a temperature below that of the peritectoid reaction.²⁰ The adjustment of the composition of the terminal solid solution was more complete at the slower rates of heating, and a corresponding contraction before the start of the peritectoid transformation was found at the slower rates of heating.⁸ Extrapolation curves of the opposite curvature have been found, for which similar explanations can be advanced. However, most of the curves have not shown a maximum (as in Fig. 7) or a minimum, but the explanations of the shape of the extrapolation curves have given greater confidence in the interpretation and the accuracy of the results.

Only the extrapolated dilatometer results are given in Tables III to V. The results for all of the Co-Cr alloys in Table II are not completely satisfactory because of the segregation in some of these alloys discussed earlier. In every case, however, the transformation of the face-centered cubic cobalt (α) to the high temperature form (γ) was observed at temperatures which increased with the chromium content. The alloy with a nominal content of 35 pct Cr (which analyzed 26.9 pct at one end) transformed over the range 1275° to 1325°C, suggesting that at some point the composition extended sufficiently far on the chromium side to include the peritectoid reaction at 1323°C:

δ is the high temperature form of the compound Co_2Cr_8 shown in Fig. 2. Single crystals of alloys 5500 were examined by Dickins, Douglas, and Taylor²⁰ and shown to have the same structure as the σ phase in the Fe-Cr alloys, leaving γ available for the high temperature form of cobalt.

The alloy 4500 contained 37.3 pct Cr at one end and 38.8 pct at the other after casting, and this is reflected in the more consistent results. The last two alloys in Table II were uniform in composition and hence gave the most reliable results. The length changes refer to the change over the transformation on heating.

The structure of the 35.6 pct Mo alloy confirmed that it was very near the eutectic composition, in agreement with the diagram of Sykes and Graff shown in Fig. 1. Hence the temperatures of the start and the finish of the transformation must be

for two different reactions because if they referred to the same reaction these two temperatures should be the same at zero rate of heating. Comparison with Fig. 1 shows that the 1205°C reaction must be the peritectoid by which θ phase forms, placed at 1200°C by Sykes and Graff,⁵ and the reaction at 1240°C must be the formation of α cobalt from γ cobalt by a peritectoid reaction, which was placed at 1310°C by Sykes and Graff. This temperature is consistent with the α/γ transformation in cobalt and in the 20.3 pct Mo alloy.

Co-Cr Diagram

Fig. 8 shows the changes proposed in the Co-Cr diagram. The liquidus agrees well with the earlier results of Wever and Haschimoto² used by Elsea, Westerman, and Manning.⁷ The solidus was placed a little higher on the basis of one result, but this seems likely because Wever and Haschimoto used a cooling rate of 60°C per min. The eutectic has been placed at 1401°C with a composition of 42.5 pct Cr, because the microstructure of alloy 4200 showed γ cobalt to be present in very small quantities as the primary phase. The peritectic at 1472°C by which δ phase forms was first suggested by

Fig. 9—Co-Mo diagram with proposed modifications.

Elsea, Westerman, and Manning. The composition of the liquid taking part in this reaction is 53 pct Cr.

The α to γ transformation temperatures were not reliable in all cases because of segregation in the ingots used (only the thermal analysis results on alloys with approximately the nominal composition have been plotted in Fig. 8). The dilatometer results for a 20 pct Cr alloy containing manganese and other impurities has also been plotted by open circles. The peritectoid temperature has been placed at 1323°C as stated earlier. The existence of this peritectoid explains the apparent minimum in the solubility of δ phase in the cobalt solid solution at 1325°C which was shown in Fig. 2. The peritectoid by which σ phase forms from δ phase has been placed at 1285°C, against 1310°C given by the earlier investigation,⁷ but the latter was determined by quenching experiments in which the δ phase was not retained. Strong thermal arrests have previously been reported at 1271°C⁴ and 1275°C,² although on alloys of lower purity. A peritectoid at 1285°C is consistent with the transformation starting at 1270°C in a σ phase alloy containing 53.3 pct Cr.

Fig. 10—The liquidus surface.

The solid solubility boundary of α and $\alpha + \sigma$ found by Elsea, Westerman, and Manning⁷ has been confirmed at one point.

Co-Mo Diagram

Only two alloys were made in this system and were intended to check the position of the α/γ transformation. The liquidus and solidus at 21 pct Mo were placed 5°C higher than in earlier work,⁶ but the eutectic temperature was placed 15° lower, at 1345°C. The eutectic composition was on the cobalt side of the alloy containing 35.6 pct Mo and was placed at 35 pct.

The dilatometer results were interpreted to indicate that the α to γ transformation temperatures rise with an increase in the molybdenum content, through 1221° to 1226°C at 20.3 pct Mo to the peritectoid at 1240°C:

This was consistent with the solid solubility boundaries fixed by Sykes and Graff.⁵ The transformation at 1205°C must be the peritectoid reaction by which θ phase forms (see Fig. 9), by comparison with the earlier diagram.

Ternary System

In all cases the dilatometric investigation at the fastest rate of heating was made to a temperature a little below the solidus unless this was in excess of 1400°C. The thermal analysis on cooling was usually stopped at a temperature a little below the liquidus, and the solidus temperature was determined by thermal analysis on heating. In one case, however, a transformation was detected by both methods. Thermal analysis placed the σ/δ transformation at 1306°C on cooling for alloy 4020 (see Table II) which was later found to be between 1270° and 1310°C by dilatometry. In view of this lack of overlapping in other cases it is possible to consider these results in four groups: the liquidus surface; the solidus surface; the α/γ transformation, and the σ/δ transformation. Although indications were obtained directly of some of the solid solubility boundaries, these were inadequate for the construction of a complete ternary diagram.

Liquidus Surface: This is shown in Fig. 10 and includes the results from 34 alloys. One characteristic of the surface at which γ cobalt begins to sepa-

rate is the double valley, running approximately parallel to the 5 and 20 pct Cr compositions.

Arrests due to the composition of the liquid reaching a eutectic valley were observed in alloy 3015 at 1352°C and in alloy 1530 at 1331°C. A prolonged arrest was observed in six alloys: 0530 (1333°); 0540 (1334°); 0550 (1333°); 1530 (1327°); 1535 (1330°); and 2030 (1327.5°C). The arrest at 1330° in alloy 1535 was the only one observed suggesting that this alloy approximates to the ternary eutectic composition. On the other hand, the systematic decrease in the eutectic temperature with increase in the chromium content was also found in the heating curves; 0530 (1332°); 0540 (1330°); 1530 (1324°); and 1535 (1322.5°C). However, a preliminary survey by X-ray diffraction on the chill cast alloys had not revealed the presence of any ternary compounds so that it was assumed that alloys 0530, 0540, and 0550 were outside the ternary fields. The ternary eutectic was placed at 1325°C and at a composition of 11 pct Cr and 34 pct Mo, where the reaction was:

The publication⁹ of details of a new intermetallic compound at a composition surrounding 20 pct Cr-

Fig. 11—The α/γ transformation surfaces. The solid lines represent the γ side and the dotted lines the α side of the $\alpha + \gamma$ field.

40 pct Mo makes it necessary to reconsider this assumption. It might be possible for two invariant points to exist, for example:

and:

where R is the new intermetallic phase.⁹ These two nonvariant points would be close together and would require a second break in the surface running towards the Cr-Mo binary system. The liquidus surface was not investigated in detail in this area because the investigation was restricted to cobalt-rich alloys, so that no evidence is available from this source and confirmation of this question must await further work. Two pieces of evidence which did not support the existence of a second invariant point were the absence of a eutectic arrest in alloy 2530 and the X-ray diffraction examination of chill-cast alloy 2040 which revealed only σ and ϵ phases.

The only other arrest recorded in Table II is at 1442.5°C in alloy 1050. This is believed to be the same peritectic as that found earlier in the Co-Mo system at 1550°C where:

$$L + \gamma = \epsilon \text{ (see Fig. 1)}$$

The α/γ transformation is plotted in Fig. 11 which shows the projection of isothermal sections at 1300°, 1275°, 1250°, 1225°, 1200°, 1175°, 1150°, and 1125°C on to the diagram (the 1150° and 1200°C sections on the molybdenum-rich side are omitted for clarity). The falling temperatures and length changes suggested a ternary eutectoid at 1079°C, but this viewpoint will have to be examined anew in the light of the recent claim that a ternary compound exists.⁹ The unexplained yet marked reaction at 1198°C in alloy 1530 (see Table V) and the inconclusive results obtained with alloy 2530 which was also expected to be in the ternary field and exhibit the 1079°C reaction, both suggested that the ternary field was more complicated than that shown in Fig. 11. The transformation surfaces between the γ and α fields will be unaffected by any small changes in this region, however.

The σ/δ transformation was detected in nine alloys by dilatometry and in one of these (4020) it was confirmed by thermal analysis. Although a slight rise in the transformation temperature was found on moving from alloy 4200 to 3805 (from 1285° to the range 1289° to 1300°C), the general tendency was for a fall in temperature on the δ side of the transformation field. The flatness of the lower surface of this field makes it impossible to predict the reactions by which σ forms from δ in the two or three-phase alloys. The solubility of molybdenum in σ phase appears to be between 20 and 25 pct at these temperatures, in agreement with the measured expansion of the plane spacings of the σ phase in chill-cast alloy 2040.

Discussion of Results

The liquidus and solidus surfaces at the cobalt corner of the diagram are characterized by a marked depression along the 5 pct Cr composition line, revealed by alloys 0512 and 0520. With higher chromium contents the liquidus and solidus surfaces diverge giving a maximum freezing range of 68°C in alloy 0822. Towards the Co-Cr side of the diagram, the surfaces approach each other again so that the freezing range of alloy 2905 is 15° to 20°C. This is in conformity with the observed smaller freezing range in which γ phase solidifies from Co-Cr melts.

The valleys in the transformation surfaces of γ to α phase running down from the cobalt corner were confirmed by three alloys with transformation temperatures below those for pure cobalt (1119° to 1145°C). These were 1010, 0520, and 0822 and these point towards the 1079°C reaction in the alloy 1530 being the ternary eutectoid by which γ decomposes to α plus two other phases. The reaction which extrapolated to a starting temperature of 1198° and to a finishing temperature of 1199°C is also believed to be that of another four-phase, nonvariant, equilibrium. The phases involved may be θ (see Fig. 1), γ , ϵ , σ , or R . The absence of any reaction involving θ in alloys 0530, 0540, and 0550 suggests that it is an equilibrium between the last four phases, probably involving the formation, or the decomposition, of R phase.

The temperature of the peritectic reaction $\gamma + \delta =$

α which is at 1323°C in the Co-Cr binary system, falls sharply with the addition of molybdenum, whereas the peritectic reaction $\alpha + \delta = \sigma$ at 1285°C in the binary system occurs at slightly higher temperatures as small amounts of the third element are added. This leads to a nonvariant point of equilibrium between the four phases at 1288°C, and at a composition of 42 pct Cr and 1.5 pct Mo.

Conclusions

In this work particular attention has been paid to the α to γ , and to the σ to δ transformations. Both of these transformations are easily overlooked in quenched specimens, although Sykes and Graff⁵ published micrographs of the α phase in the Co-Mo system drawing attention to the marking on the grains, and Elsea, Westerman, and Manning⁷ observed the precipitate left as a result of a change of solubility of α phase during the decomposition of δ to σ in the Co-Cr system. Both methods are of restricted use and, even then, uncertain.

These results, then, support the widely accepted view that more than one method of examination should be used in the study of constitution diagrams and reaffirm a corollary that one of these methods should involve observations at temperature.

Acknowledgment

This work would not have been possible without the active interest and encouragement of Professor Wesley Austin to whom considerable thanks are due. It is a pleasure to acknowledge the help provided by many outside organizations, especially the financial assistance provided by the Rhokana Corp.

Residual Stresses Introduced During Metal Fabrication

by Kent R. Van Horn

RESIDUAL stresses in metals operate under a cloak of mystery, as they have neither been seen in the laboratory nor detected by means of the microscope. In spite of their phantom-like nature, they frequently exert metallurgical effects that cannot be ignored. In some cases the results have been detrimental, causing rejections or premature failures, but frequently the effects have been highly beneficial to the producer or consumer of metal products. First, however, what is a residual stress?

When a metal is plastically deformed by bending, rolling, pressing, or by a phase transformation or precipitation from solid solution, or by a sharp temperature gradient resulting from nonuniform cooling, quenching, or welding, it remains in a state of strain. The strains or strain gradients produced by such operations and retained after all external forces are released are known as residual strains, and the accompanying stresses as internal or residual stresses.

Many defects or failures in metal products have been ascribed to residual stresses, sometimes erroneously, because there was no other apparent explanation after the usual metallurgical tools of diagnosis had been applied. For example, during World War II, the forged aluminum alloy aircraft cylinder head in the reciprocating engine began to replace the cast head with the familiar cooling fins. The fins were machined in the solid forged head by an ingenious milling operation. One plant reported an epidemic of excessive distortion during the delicate

high-speed milling. A thorough examination revealed that the composition, heat treatment, mechanical properties, and metallurgical quality of these heads were comparable to those of forgings that machined satisfactorily. It was then claimed that the cause of the machining difficulties was connected with residual stresses resulting from the quenching during the solution heat treatment. An elaborate stress analysis actually demonstrated, however, that the magnitude of residual cooling stresses was lower in the cylinder heads which machined poorly than in those which were satisfactory in this respect. Subsequent tests proved that the machining problems in this case originated from variations in the tools and tool design.

Sources of Residual Stresses in Metals

Residual stresses are of two origins—mechanical and thermal. Thus, stresses may be produced in a metal by any cold-working process. The distribution and magnitude of these mechanically produced stresses can be calculated in a satisfactory, although approximate, manner for such simple cases as bending, torsion, and expanding of tubes. However, most manufacturing processes are too complex, and the original stress-strain relations in the products are not sufficiently known to permit calculation of the resulting residual stresses. Also, a specific process, such as wire drawing, may vary in complexity or uniformity of working, and large or small residual stresses may result, depending on the conformation of the dies and other features of the working process. Neither substantially unidirectional deformation, such as can be imparted by stretching a metal product having essentially the same mechanical properties throughout the cross section, nor deformation

Fig. 1a—Stress corrosion crack in surface of tubular spar chord cold-worked after heat treatment. X5. Area reduced approximately 35 pct for reproduction.

Fig. 1b—Macrograph of crack revealed in (a) just below the surface. Crack is parallel to axis of tube. E. H. Dix, Jr.⁵ X20. Area reduced approximately 35 pct for reproduction.

at sufficiently high temperatures followed by slow cooling will create appreciable residual stress.

At sufficiently high temperatures, residual stresses are relieved by plastic flow. Thus, stresses introduced by cold working during fabrication are erased during a high temperature heat treatment; but the subsequent cooling may or may not produce new stresses, depending on the rate of cooling. A metal piece heated and then cooled very slowly remains free from appreciable stresses. Furthermore, as long as the magnitude of any stress is less than the elastic limit at the specific temperature, the stresses are dependent only on temperature gradients and disappear completely on cooling to room temperature or an equalized temperature. The distribution and magnitude of the stresses may be appreciably affected if some sections yield during either heating or cooling. These direct thermal stresses are an important cause of the cracking in steels, which may occur in an article undergoing temperature changes. During quenching the colder surface zones are stretched beyond the yield strength because their normal thermal contraction is restricted by the retarded contraction of the hotter interior zones. When the temperature of the interior zones subsequently approaches that of the surface layers, the previous permanent stretch results in compressive stresses in the outer zones when they attempt to follow the delayed thermal contraction at the interior. This leads to the im-

portant generalization that the portions which cool more rapidly retain compressive stresses, whereas the portions which are the last to attain room temperature contain balancing residual tensile stresses; that is, in a rapidly cooled part the surface layers generally contain residual compressive stresses and the core or center tensile stresses. Thus, solution heat-treated aluminum alloy products and many heat-treated products of other metals contain compressive stresses in the exterior layers. This is a highly advantageous stress distribution for the accommodation of external service loads, whereas residual surface tensile stresses, on the contrary, would normally be additive to the service stresses and contribute to cracking or failure. Of course, the residual stress pattern of heat-treated and quenched products may be rearranged by subsequent machining or cold-working operations. Also, the conventional distribution resulting from thermal contraction during quenching may be considerably distorted if a phase transformation interferes with the thermal contraction, as in some carbon steels. Thus, residual tensile stresses can be produced in surface layers of certain quenched steels and, depending on the magnitude, may even cause quenching cracks.

A variety of residual stresses are derived indirectly from deformations produced during cooling. These cooling stresses may originate from, 1—quenching, 2—phase transformation, 3—constituent precipitation, 4—welding, and 5—casting (generally low compared to other sources). All of these stresses result from nonuniform thermal contraction or a volume change during a phase transformation, within the temperature range of cold work.

There are, of course, many comprehensive surveys of the origin of residual stresses in metals available in the literature.^{1, 2}

Beneficial and Detrimental Residual Stresses

Residual stresses are frequently suggested as likely sources for some of the difficulties encountered in the machine shop or fabricating plant. In fact, many designers consider residual stresses to be undesirable and believe that procedures should be initiated to eliminate residual stresses in metal products at any cost. Whether or not the residual stresses are actually undesirable can only be ascertained by stress analysis, which may be expensive and sometimes impossible. Castings, extrusions, or forgings generally have complex shapes that do not permit analysis of the stress distribution. The measurement of residual stresses in metals is more difficult, as a general rule, than the determination of the effects of external or service loads.

Residual stresses may have a beneficial as well as a deleterious effect. Some of the advantages of residual stresses that have been commercially utilized have been summarized by your lecturer and Dr. G. Sachs:¹

1—Stresses produced by plastic expansion are used to increase the strength of gun barrels and pressure vessels (auto fretting). The strength of rotating wheels can also be enhanced by a previous overloading.

2—Stresses imposed by shrink fitting are also employed to increase the strength of gun barrels.

3—Stresses formed by shrink fitting or the introduction of inserts are utilized to improve the service life of extrusion cylinders, forging dies, and drawing dies.

4—Stresses introduced by the quenching of most metal parts probably have a beneficial effect on the fatigue strength.

5—Stresses derived from local deformations produced by mechanical surface treatments, such as surface rolling, shot or hammer peening, ball pressing, etc., reduce to a considerable extent the injurious effects of notches, corrosion, and chafing on the fatigue strength.

6—Stresses resulting from stretching, bending, twisting, and overloads in various types of service applications are used to advantage.

In most of these applications residual compressive stresses are formed in the surface layers where high tensile stresses may be produced by the service loads. The beneficial stresses decrease the magnitude of the resultant surface stress in the case of a static loading; and in fatigue the mean stress in the fatigue cycle is displaced toward the compression side of the stress diagram, resulting in an improvement in fatigue life.

The principal detrimental effects that may accompany residual stress are briefly enumerated:

1—Warping or distortion during machining is related to the magnitude of the residual stresses, their distribution, and the quantity and location of the removed metal or the overloading of the part in the fixture.

2—Fire cracking and stress cracking may occur during the soldering and brazing of cold-worked steels and copper alloys.

3—Materials quenched for the purpose of hardening, such as steels and the aluminum alloys, may crack during or after quenching.

4—Castings and ingots may crack on cooling, storing, or reheating.

5—Fusion-welded structures may crack during welding or in service.

6—Certain alloys, subjected to mild corrosion, crack when sufficiently high surface tensile stresses are present.

7—Steel boilers, subjected to corrosion under stress, crack around riveted or otherwise deformed locations.

The different types of cracking originating from residual stresses have been traced in every case to the presence of high tensile stresses at the point of failure. Some of the cracking phenomena, however, are the result of stresses created by external forces.

Wishart³ and Richards⁴ have recently published comprehensive descriptions of the residual stresses in certain metal products and the mechanical or thermal procedures for producing beneficial or detrimental stresses.

Typical Examples of Residual Stress

Investigation in Metals

Many investigations have been conducted to determine the magnitude and distribution of residual stresses in metal products, to develop methods of stress analysis, to discover practices to reduce or eliminate detrimental stresses, and to develop procedures to impose the type of stresses that would improve the serviceability of the part. Most of this work probably has been done by mechanical engineers rather than by metallurgists. Thus, since 1928, when the papers of the Institute of Metals Division were assembled in a separate volume, there have been only seven papers published on this subject.

Fig. 2—Season cracking in a brass tube. Courtesy of D. K. Crampton.

The record of the *Transactions* of the American Society for Metals is six papers from 1928 to 1951. This is indeed surprising because of the acute and continuous interest over the years in residual stresses in so many plants that produce, fabricate, or use metals.

Most of the investigations were probably initiated because a part had failed in service and procedures had to be developed to remedy the situation. Several typical investigations of specific interest to the majority of the readers and to the important air-frame industry will be described.

Aluminum alloy square tubes were used in the main spar trusses of four-engine airplanes. For ease of fabrication these tubes were manufactured originally as round tubes and then sunk (without a mandrel) to the square shape. With the objective of obtaining maximum tensile properties, this sink from the round to the square tube was performed at room temperature on the completely heat-treated material, thus introducing additional cold work, which resulted in high mechanical properties. However, the plastic deformation also produced a high level of residual tensile stresses on the external surface of the tubes.* The tubes met all chemical and me-

* In contrast to the high stresses in tubes produced by cold sinking after solution heat treatment, 24S-T36 sheet which is cold-rolled after solution heat treatment possesses a low level of residual stress.

chanical property specifications and seemed entirely satisfactory for service. Unfortunately, mysterious longitudinal cracks developed in service, Fig. 1. Subsequent fatigue tests of full sections of tube, employing a beam-type specimen with two-point loading, revealed no deleterious effects from the residual stresses.

A laboratory examination of the tubes revealed that the cracks were of an intergranular nature, which suggested that stress corrosion was the cause.⁵ This was confirmed by stress corrosion tests which duplicated the type of crack that occurred in service. Also, stress analysis was possible because of the

Fig. 3—Effect of copper content on the magnitude of the residual tensile stress, the Rockwell hardness, and the tendency to season crack in brass tubes sunk from 1.0x0.060 in. to 0.813 in. D. K. Crampton.⁶

relatively simple shape of the tube. The investigation revealed that the residual stress level in the tubes, resulting from the manufacturing process, was extremely high, in many cases as high as 65,000 psi tension, the yield strength of the alloy. This level of residual stress was so high that cracking occurred after a period of time, even when painted tubes were exposed only to ordinary atmospheric conditions. All efforts to prevent cracking by protective films proved futile, and this problem was solved by altering the manufacturing practice to reduce the magnitude of the residual stresses. The change involved was to heat treat after the tube was drawn square, so as to alleviate the residual stresses introduced by drawing from the round to the square shape. No further cracks were encountered in service after this practice was adopted; however, some reduction occurred in the final mechanical properties of the tubes.

This example concerned residual stresses in an aluminum alloy product. However, the occurrence of detrimental residual stresses is not restricted to aluminum alloys but may be characteristic of any metal subjected to certain fabricating conditions. In fact, probably the first recognition of residual stress effects and the principal impetus to the early work in this field resulted from the premature failure in service of brass products possessing residual stresses. Cracking was observed to be most pronounced in cold-worked brasses and to occur occasionally even in the absence of applied loads. This phenomenon, known as season cracking, was detected in brass and copper alloy tubes, Fig. 2, but later was found to occur occasionally in other metals.

Season cracking in brass may be initiated by vibration, oxidation, weathering, and especially by attack of ammonia or compounds of mercury. The cracking tendency in brass increases with the content of zinc (with brasses containing over 20 pct zinc) and depends upon the magnitude of residual stresses.⁶ Fig. 3 from Crampton shows the relation of the composition of brass tubes to the tendency to crack, while Fig. 4 illustrates the effect of the degree of sinking on the magnitude of the residual tensile stress (mechanically produced) and the tendency to season crack in high brass tubes.⁶ Because of the unsatisfactory character of the data procured from the earlier mechanical sectioning methods of stress analysis, the exact relation between the magnitude or distribution of the residual stress and the tendency to crack has not yet been determined. One expert claimed that a certain type of stress is significant, while another considered that a specific type of stress distribution is detrimental. However, the practical solution to the problem was attained by the selection of immune brass compositions and the introduction of annealing treatments at temperatures that did

not produce appreciable softening but reduced the residual stresses to values which were within safe limits.

Residual stresses are produced in the cold drawing of steel rods, and may be high under certain conditions. They may even cause failure of the rods when service stresses are imposed along with even slight corrosive attack, or during machining. The residual stresses can be decreased by slight heating (softening) after drawing; however, this may result in an undesirable reduction in the strength and hardness which were provided by the drawing. A recent investigation⁷ revealed that a different distribution of residual stresses could be obtained in drawing steel rods than was previously experienced. Thus, compressive stresses in the interior and tensile stresses in the exterior zones of drawn rods were observed in former experiments. However, Bühler found that the reverse could be obtained, with slight reductions in cross section, by drawing in the opposite direction or pushing through the die. This practice was utilized to reduce the magnitude of residual stresses of drawn rods without any sacrifice in the mechanical properties. Thus, a 0.19 pct carbon steel possessed an 80,000 psi longitudinal tensile stress and 46,000 psi tangential tensile stress at the surface after drawing from 1.9 to 1.8 in. diameter. A subsequent cold reduction of 2.2 pct obtained by pushing through the die, reduced these values to 15,000 and 10,000 psi, respectively.

Among the frequent sources of failure in hardened steel are quenching cracks, Fig. 5. The origin of cracks during quenching of tool steels from the heat-treating temperature was investigated by Scott,⁸ who demonstrated that the cracks occurred at surface locations where tensile stresses existed. Scott concluded that tensile stresses at the surface were the result of expansion during the transformation. This effect was more prominent in the specific steels investigated than the stresses formed by deformation arising from contraction on cooling. Scott was able to recommend practical expedients for the control of residual stresses in tool steels and to minimize the quenching cracks. The familiar grinding cracks in steels were also demonstrated by Scott to be the result of tempering of the surface under the grinding wheel, reducing the volume of surface metal and thereby producing surface tensile stresses. Again the cracks occurred in surface layers where high tensile stresses existed.

Methods of Measuring Residual Stress

Residual stresses are generally measured by either mechanical or X-ray methods, although other means have been employed. Unfortunately, the mechanical methods, although extensively used, are destructive in that the procedures consist of removing metal by machining, sawing, drilling, grinding, or etching, and measuring the resulting elastic deformation of the remaining section. X-ray analysis of residual stresses, although nondestructive, has the disadvantage of giving only approximate surface stresses. Surface stresses are often important, but in many applications it is equally necessary to determine the distribution and magnitude of residual stresses in the interior of the section.

In this lecture it is only possible merely to enumerate the available methods for measuring residual stresses, and not to give a detailed description of the theory and techniques of the various procedures. Excellent reviews have been published by Barrett,⁹

Ford,¹⁰ Baldwin,¹¹ Horger,¹² Sachs,^{1, 13} and Lynch,¹⁴ and in the other references to be subsequently cited. Emphasis will be directed toward the methods that are applicable to differently shaped fabricated products, such as solid cylinders, thick or thin-wall tubes, rods, bars, or plates, and to an appraisal of the accuracy of the methods.

Methods for Solid Cylinders and Thick-Wall Tubes: The residual stresses in solid cylinders and thick-wall tubes have been successfully determined by numerous investigators by the Sachs method.^{1, 13, 15} The procedure consists of boring on a lathe or drilling out, in small cuts, the interior of a solid cylinder or tube having a length at least three times its

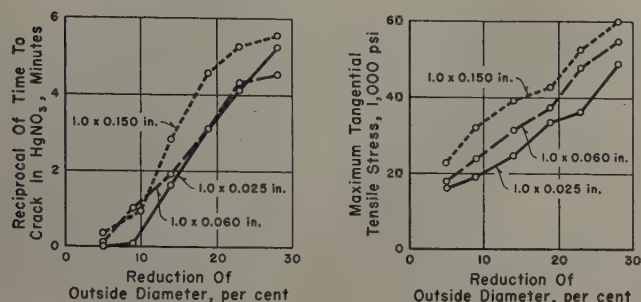

Fig. 4—Effect of degree of reduction by sinking on the magnitude of the residual tensile stress and the tendency to season crack in high-brass tubes. D. K. Crampton.⁹

diameter, and measuring the elastic deformation resulting from each boring operation. The recent use of SR-4 electrical strain gages, cemented longitudinally and circumferentially on the exterior surface of the cylinder, has appreciably improved the accuracy of the measurements.

This method permits determination of the three principal stresses in a cylinder. The equations formulated for these stresses are based on the slopes of the curves obtained by plotting deformation (measured changes in dimensions) against bored-out cross section, and are, therefore, subject to some error. Bühler and Schreiber¹⁶ developed a procedure wherein an analytical rather than graphical development of the curves from the data points was employed in an effort to obtain more precise values for the slopes.

With appropriate modifications, the method can also be applied to the removal of metal from the outside surface of a tube or partially bored-out cylinder. Hanslip¹⁷ developed a technique for locating SR-4 gages on the inside surface.

Method for Longitudinal Stresses in Rods, Tubes, and Rails: Where the dominant residual stresses in rods, tubes, and rails are longitudinal in direction, the stresses can be determined easily, although only approximately, by slotting the member longitudinally into many strips of small cross section and measuring the change in length of each strip individually.¹⁸

Methods for Thin-Wall Tubes: Residual stresses in thin-wall tubes can be obtained by rather simple methods,¹⁹ if the stresses consist of high tensile stresses at the inner or outer surface and high compressive stresses at the other surface. Tangential stresses are evaluated from the change in diameter that occurs at mid-length when a section of tube having a length of at least three diameters is split longitudinally. The deflection resulting from the cut-

ting of a circumferential tongue can also be used. Longitudinal stresses can be obtained from the deflection of a longitudinal tongue. It is generally accepted that the results procured by this procedure permit only an approximate evaluation of the stresses in the tube even when the stresses approach a linear distribution through the thickness. The results are considered to be inaccurate for nonlinear stress distributions.

A more elaborate quantitative method for the determination of residual stresses in thin-wall tube extends the simple procedure described to specimens from which successive surface layers have been removed by machining or etching.

Methods for Bars and Plates: Various methods have been proposed to investigate the stresses in bars and plates. Where the stresses are reasonably uniform through the thickness of a plate, a suitable number of small pieces, oriented in the direction of the principal stresses, are cut from the plate. Each section should contain appropriate gage marks or SR-4 strain gages on which measurements are made before and after the removal of the pieces.^{20, 21} If each piece contains only a single gage line, the sections should always be cut in pairs normal to each other, in order to evaluate the biaxial stress conditions in the plate. Another practice is to employ double gage lines, perpendicular to each other, inscribed on each piece. When the directions of the principal stresses are unknown, a rosette method is used with three or more strain measurements made at appropriate angles to each other to permit determination of the magnitude and direction of the principal stresses. Agreement has not yet been reached as to the most satisfactory type of cut-out pieces for this method.

When the stress distribution through the thickness of a bar is desired, the usual procedure is to remove layers from one side of the bar by machining or etching and measure the elastic deformation of the bar after the removal of each layer.^{22, 23} The deformation of the bar can be determined either by a

sagitta gage, which measures the middle ordinate of a known chord, or by SR-4 gages cemented to the side opposite to the one being machined.

Combinations of these methods can also be adapted for the determination of residual stresses throughout the thickness of a plate.²⁴ Narrow blocks are removed from the plate in the directions of the principal stresses, and then the strains remaining in the blocks are relaxed by removing thin layers from one side. By adding to the residual strain distribution (obtained from the layer-removal method) the strain distribution relieved when the block is removed from the plate, it is possible to calculate the residual stresses. By selecting blocks in two or more directions, the biaxial stress conditions in the original plate can be evaluated.

In the case of sheet, the magnitude and distribution of biaxial stresses through the thickness may be determined by removing thin layers from one surface of the sheet and measuring the change in curvature of the sheet in the direction of the principal stresses.²⁵

Methods of Determining Residual Stresses by Measuring Deformation Around Drilled Holes: A mechanical method for determining residual stresses which does not completely destroy the part to be investigated was devised by Mathar.²⁶ Basically, the procedure consists of drilling a hole and measuring the deformation on the surface of the metal adjacent to the hole. Mathar employed a mechanical extensometer, and therefore the precision of the results may be questioned. Subsequent work indicated that the use of electrical-resistance strain gages offers more promise for this method. At present, the procedure is restricted to surface stresses or to applications where the stresses are approximately uniform through the thickness.^{26, 27} The method has not as yet been extended to the determination of stress distribution where the values vary with depth.

A rapid qualitative survey of residual stresses can be obtained by the use of brittle lacquer to reveal the nature of the stresses relieved by drilling a hole.²⁸ This procedure will indicate the locations of appreciable residual stresses, the directions of the stresses, and the type of stress at each point.

X-ray Diffraction Methods: The X-ray diffraction method for measuring residual stresses has received considerable attention in recent years.²⁹⁻³¹ In this procedure it is possible to measure the distance between atoms in metal crystals; the interatomic dis-

tance is then used as a gage length for the determination of elastic strains. There are numerous modifications that permit the measurement of the sum of the principal stresses at the surface, or the stress component in any direction in the surface layer, or the direction and magnitude of the principal stresses at the surface. The method has the advantage of being nondestructive but is limited to determining the stresses at the metal surface. At-

Fig. 7—Effect of quenching rate on the maximum residual longitudinal tensile stress in alloy 14S and 355 cylinders, 3.0x9.0 in., quenched from 935° and 980°F, respectively, in various media.

tempts have been made to measure stresses below the surface by determining strains at the bottom of a drilled hole, but it is thought that such a procedure is not reliable because of the stresses relieved by drilling the hole, and the possible localized deformation of the metal during machining.

Other Methods: Methods other than mechanical or X-ray diffraction have occasionally been utilized to determine residual stresses. Measurements of magnetic properties, electrical resistivity, and internal friction have been used and are, in general, qualitative in nature.³²

Critical Appraisal of Methods for Measuring Residual Stresses

The mechanical methods of determining residual stresses require that the stress equilibrium be disturbed and readjusted by removing metal, and the resulting elastic deformation of the remaining section measured. It is realized, of course, that the mechanical methods are accurate only if no stresses are introduced or relieved by the removal operation itself. Since the metal is generally removed by machining, sawing, drilling, boring, or grinding, some doubt exists as to the reliability of the results obtained from these methods.³³ Etching has been employed to remove metal, but there is the possibility of chemical attack along the grain boundaries of a surface containing residual tensile stresses, which would relieve stresses to a greater depth than intended.

The machining operations used in the mechanical methods tend to increase the temperature of the part being machined. Precautions should be exercised to reduce to a minimum any change in temperature. It is also important that the strains be measured at a constant temperature or that adequate

corrections be applied for any room temperature variations.

Where residual stresses are determined by the removal of successive layers, it is assumed that the stress is uniform throughout the thickness of the layer. This assumption may cause erroneous results where a sharp stress gradient exists. Such gradients occur, for example, at a shot-blasted surface where the stress changes from a high residual compressive

Fig. 8—Cooling rates on alloy 61S sections, 2.25x3.0x7.0 in., quenched from 970°F in various media.

stress at the surface to a relatively low tensile stress at a distance of about 0.020 to 0.030 in. below the surface. Steep stress gradients may also exist on the surface of roller leveled plate. When the stresses in such a plate are determined by removing small sections from the plate, it is desirable that the piece be as small as possible. One limitation on the length of the piece is the gage length by which the strains are measured. For this reason, electrical-resistance strain gages, having an effective gage length as small as 0.06 in., offer a decided advantage over the hand-type mechanical strain gages, where the smallest gage length available for this type of work is about 2.0 in.

The mechanical methods of measuring residual stresses are based on various assumptions, and therefore it is imperative that the limitations of the different procedures are recognized. For example, the Sachs boring-out method, requiring the selection of a cylinder or tube having a length at least three times its diameter, assumes that the stresses have rotational symmetry about the axis and are uniform along the length. If this were not the case, the results would represent only some mean value of the actual stresses.

Not only will the accuracy of the results obtained by the mechanical methods vary with the procedure employed, but the accuracy will also be affected by the dimensions or geometry of the piece to be investigated and the magnitude and distribution of the stresses. For example, the residual stresses were determined in a 0.5x0.75x6.0 in. block from alloy 75S-W as-heat-treated rolled plate by the layer-removal method. Successive layers were machined from the 0.5x6.0 in. surface, the thickness of the first layer being 0.025 in. The strain relaxed on the side opposite the one being machined by the removal of the first layer was 100 microin. per in., equivalent to an average of 14,000 psi compression in the layer removed. Calculations revealed that if the error in

this measured strain was ± 10 microin. per in. and the error in measuring the thickness of the block before and after the removal of the layer was ± 0.0005 in., the residual compressive stress in the layer removed would be between 12,000 and 16,000 psi.

Since the X-ray method is restricted to the measurement of stresses on the surface, and the mechanical methods require extrapolation of stresses to the surface, it is difficult to compare the two procedures and appraise the relative accuracy. The X-ray method requires a refined technique in preparing the metal surface and in making the measurements. The metal must be fine-grained, of uniform composition, and free of minute stress variations. If the grain size is too large, the diffraction lines are spotty or not of uniform width, and therefore cannot be measured precisely. On the contrary, a grain size which is too fine produces broad lines and consequent inaccuracy. Thomas³⁰ compared the stresses measured by X-rays in steel with mechanically imposed stress values and found that the stresses obtained from the X-ray were about 30 pct higher than those calculated from the actual loads. Some of the possible sources of error in the X-ray method were encountered in this investigation, so that the total discrepancy may not be representative of the optimum conditions for X-ray diffraction. Under conditions giving sharp diffraction circles, the line widths can be measured with a precision of about ± 0.01 in., representing an accuracy in stress values of $\pm 1,500$ psi. As the line becomes broader, the precision decreases considerably.³⁰

Effects of Fabricating Practices on the Residual Stresses in Aluminum Alloys

The majority of the investigations involving the determination of residual stresses in fabricated metal products was initiated because of the failure, cracking, or excessive distortion of a part, and the possibility that residual stresses contributed to, or were responsible for, the difficulty. Thus, exhaustive qualitative investigations have been conducted on axles, gears, propellers, spars, tubing, and weldments. In general, mechanical methods of stress analysis were employed, and usually the results culminated in the adoption of a different fabricating practice. There have been few quantitative investigations of the effects of various fabricating conditions and metallurgical factors on the magnitude and distribution of residual stress in metals published in this coun-

Fig. 9—Effect of surface treatment on the magnitude of the residual stresses in alloy 14S cylinders, 7.0x7.0 in., quenched from 940°F in boiling or cold water.

try. However, the literature reveals that there have been extensive investigations conducted on various steels in Germany.

This lecture will report briefly on an investigation of the effects of quenching temperature, quenching rate, section size, composition, and tensile properties on the magnitude of residual stresses in cast and wrought aluminum alloy products. In addition, the effects of reheating time and temperature on the magnitude and distribution of retained stresses will be discussed. Although the work was performed on aluminum alloys, the significance of the various fabricating factors and the general conclusions should apply to all metals. In the investigation, several hundred cylinders were analyzed by the Sachs¹⁵ boring-out method. The length of most of the cylinders was generally three times their diameter. The curved surfaces of the cylinders were machined and ground to a fine finish, while the bases were machined and finished on a lapping plate. The cylinders were measured in a constant temperature room on a comparator, standardized by the most precise type of gage blocks available. Special jigs were constructed

Fig. 10—Effect of section size on the magnitude of the residual stresses in alloy 14S cylinders quenched from 940°F in water at 70°F.

to hold the various sized cylinders rigidly during the boring operations. Care was exercised to use light cuts during boring, and auxiliary cooling was employed to prevent heating of the cylinders. The use of small cuts increased the number of measurements, thereby improving the accuracy of the data, although this practice added appreciably to the cost of the tests. The measured elastic deformations, resulting from the readjustment of stress equilibrium produced by the boring operations, were converted by the equations formulated by Sachs to longitudinal, tangential, and radial stresses. The stress distribution diagrams were all checked by planimeter measurements to determine if the stresses balanced.

Inasmuch as the high strength aluminum alloys are solution heat-treated at relatively high temperatures, the residual stresses formed during the fabrication of castings, bars, extrusions, forgings, etc. are relieved during the heat treatment. However, the quenching or cooling from the solution heat-treating temperature produces residual stresses which may be either large or negligible, depending on the various factors which will be discussed. The resulting stress pattern or distribution is always the same and relatively simple. Longitudinal and tangential compressive stresses exist in the exterior or

surface layers of solid shapes or cylinders, and tensile stresses in the core or center. The radial stresses are tensile at the axis and zero at the surface. The residual stress pattern of heat-treated hollow cylinders reveals longitudinal and tangential compressive stresses on both the exterior and interior surfaces with tensile values between. The residual stress distribution in sunk tube is, of course, different from that in quenched tube. The longitudinal and tangential stresses are tensile in the surface layers and compressive on the interior surface. The radial stresses are compressive in the intermediate layers and zero at the interior and exterior surfaces.

Effect of Quenching Temperature: The effect of quenching temperature on the magnitude of the residual stresses in alloy 56S** solid cylinders, 3.0x9.0

** The alloy and temper numbers in this paper refer to Aluminum Company of America designations. The compositions and temper treatments of the alloys are printed in the 1948 edition of *Metals Handbook* published by the ASM.

in., quenched in cold water at 76°F, is illustrated in Fig. 6. Alloy 56S, essentially a solid solution alloy at all temperatures, was selected for this experiment in order to eliminate precipitation effects during quenching. Varying the quenching temperature from 900° to 500°F decreased the rate of quenching and reduced the longitudinal and tangential compressive stresses in the surface layers of the cylinders by 25 and 13 pct, respectively, and both the longitudinal and tangential tensile stresses in the center by approximately 88 pct. The distribution diagrams also revealed that when the quenching temperature was 600°F or lower, the maximum tensile stress was displaced from the center of the cylinders.

Effect of Quenching Rate: The magnitude of the residual stresses in the quenched aluminum alloy cylinders depended directly on the cooling rate prevailing during the quench from the solution heat-treating temperature. The relation between the quenching rate and the magnitude of the residual stresses in alloy 14S and 355 solid cylinders, 3.0x9.0 in., quenched from 935° and 980°F, respectively, is represented in Fig. 7. In this illustration, only the maximum longitudinal tensile stress at the center of the cylinder was plotted. The highest residual stresses were produced when the cylinders were quenched in cold water, intermediate values when quenched in hot oil, molten salt, or hot water, and very low stresses when quenched in boiling water or by an air blast. The various quenching media employed (cold water, boiling water, oil, moving air, etc.) produced different cooling rates ranging from approximately 100°F per sec to 2°F per sec. Fig. 8 shows the cooling rates obtained for alloy 61S sections, 2.25x3.0x7.0 in., quenched from 970°F in various media.

The significant effect of the quenching rate on the magnitude of the residual stresses was again clearly demonstrated in an investigation of surface treatments on alloy 14S solid cylinders. A cylinder with a surface layer of black copper oxide, produced by the reaction of an alkaline etchant, was found to have the same cooling rate when quenched in boiling water as that of a cylinder with the coating removed when quenched in cold water. The cylinders were quenched from 940°F. Stress analysis revealed that the magnitude and distribution of the residual stresses in the two cylinders were identical, Fig. 9. This marked effect on cooling rate and stress magnitude is attributable to the wettability of the copper oxide coating. The residual stress pattern for a

similar sized cylinder with the coating removed, that was quenched in boiling water, is also included in Fig. 9.

Effect of Section Size: The effect of section size on the magnitude of the residual stresses was investigated in 2.0x6.0, 3.0x9.0, and 4.0x12.0 in. alloy 14S cylinders quenched from 940°F. Increasing the section size of cylinders quenched in water at 70°F appreciably increased the maximum longitudinal, tangential, and radial tensile stresses, and to some extent the maximum longitudinal compressive stress. The maximum tangential compressive stress values remained about the same, Fig. 10.

This effect of section size on the magnitude of the residual stresses is partially explained by the data³⁴ in Fig. 11, which records the temperatures at the center of a 0.75 in. diam rod, and at the center and other locations in a 4.0 in. diam rod, of alloy 75S during quenching from 875°F in water at 70°F. The curves show a marked temperature gradient in the 4.0 in. rod during the quench. It is revealed that the center of the 0.75 in. rod cooled much more rapidly than the center of the larger rod, in fact even faster than the surface zone of the larger rod. It may be

Fig. 11—Cooling curves for 0.75 and 4.0 in. diameter extruded alloy 75S rods quenched from 875°F in water at 70°F. Thermocouples located at various distances from center of 4.0 in. rod. W. L. Fink and L. A. Willey.³⁴

concluded that this would result in a greater, and certainly more prolonged, differential in temperature between the surface and interior zones in the larger rod than in the smaller. Thus, higher stresses would be expected in the larger rod, since the temporary difference in temperature between the center and surface zones is the basis of the formation of thermal stresses, as explained in the introductory pages of this lecture.

The effect of section size can be definitely minimized by employing a slow quenching rate, such as that provided by boiling water, Fig. 12. A comparison of Figs. 10 and 12 demonstrates the advantage of a boiling water quench for obtaining a low level of residual stress. The benefit of the boiling water is ascribed to the slow cooling rate in the critical cooling range, resulting from the prolonged occurrence of the vapor phase or envelope surrounding the cylinder.

Effect of Composition: The magnitude of the residual stresses in the solid cylinders varied considerably with the different cast and wrought aluminum alloys. Cylinders, 3.0x9.0 in., of all the alloys were quenched from the respective commercial

Fig. 12—Effect of section size on the magnitude of the residual stresses in alloy 14S cylinders quenched from 940°F in boiling water.

heat-treating temperatures in boiling water or water at 70°F.^{***} The stresses developed were considered

^{***} The cold water quench at 70°F was employed to evaluate the effect of composition factors and does not represent commercial practice for aluminum alloy castings and forgings. Therefore, the residual stresses indicated in Figs. 13 and 14, resulting from quenching alone, are appreciably higher than expected in commercial castings and forgings.

to depend on several properties or characteristics of the specific alloy. Thus, for a given strain, the higher the value for Young's modulus of elasticity, or the greater the proportional limit and yield strength of the alloy, the higher were the residual stresses, providing the other properties did not vary. Other properties which would be expected to contribute to a large strain, and therefore higher stresses, are: a high coefficient of thermal expansion, a low thermal diffusivity,[†] and a high elevated temperature yield strength.

$$\dagger \text{ Thermal diffusivity} = \frac{\text{Thermal conductivity}}{\text{Specific heat} \times \text{density}}$$

The composition factors appeared to vary in their relative influence on the magnitude of the residual stresses that were developed in the various aluminum alloy cylinders. The coefficient of thermal expansion seemed to be one of the most significant properties. For example, alloys 32S and A132 have fairly high yield strengths and the highest modulus of elasticity values, but the lowest coefficients of thermal expansion, and the stresses developed in these alloys by a water quench at 70°F were the lowest for any of the aluminum alloys investigated (17,900 psi and 20,700 psi maximum longitudinal tensile stress, respectively). Furthermore, alloy 220 with the lowest modulus of elasticity value but the highest coefficient of thermal expansion, developed high residual stresses (39,400 psi maximum longitudinal tensile stress).

The elevated temperature yield strength also appeared to be one of the potent factors. For example, alloys 14S and 142, with average values for the coefficient of thermal expansion, modulus of elasticity, and thermal diffusivity, but very high elevated temperature yield strengths, developed the highest residual stresses, when quenched in water at 70°F; of any of the aluminum alloys tested (41,250 psi and 42,950 psi maximum longitudinal tensile stress, respectively).

Effect of Tensile Strength: It is recognized that the yield strength of an alloy at that temperature during quenching, when plastic flow is completely arrested, is a significant factor affecting the magnitude of residual stresses, but such data are not available. However, some engineers may raise the

Fig. 13—Relationship of yield and tensile strength (-T4 condition) and maximum residual longitudinal tensile stress in cylinders, 3.0x9.0 in., of various aluminum forging alloys quenched from the respective commercial heat-treating temperatures in water at 70°F.

question of a relationship between residual stresses and the tensile and yield strength at room temperature. Therefore, tensile data were also obtained during the investigations of the effect of fabricating conditions on the magnitude of the residual stresses. Additional cast or wrought solid cylinders of the size used for stress analysis were simultaneously subjected to the same heat-treating, quenching, and room temperature aging procedures. Tensile test bars were machined from identical locations in the cylinders. In general, the tensile properties decreased as the rate of quenching was reduced and as the section size was increased. The magnitude of the decrease varied with the alloy. The results seemed to reveal a trend that the alloys having the higher tensile values, that is, those in the T4 condition,† contained the higher residual stresses, Figs. 13

† Quenched from solution heat-treating temperatures in water at 70°F and aged at room temperature. The aging time was three days for the casting alloys and five days or more for the wrought alloys.

and 14. This relationship was more apparent for the forging than for the casting alloys.

Distortion During Machining: When the balance between relatively high residual stresses in metal products, especially those having heavy or thin sections, is disturbed by machining, undesirable distortion or dimensional changes may result. Thus, for example, airplane cylinder muffs of alloy 142 distorted to such an extent during rough machining that the final finishing operations could not be performed. Measurements of residual stress revealed a maximum tangential compressive value of 14,000 psi in the 8.5x5.5 in. cylinders, quenched from 960°F in water at 90°F and stress-relieved 9 hr at 525°F, Fig. 15. Adoption of a boiling water quench reduced the residual stresses to a negligible amount and eliminated the distortion problems.

Difficulties were experienced by several customers in the textile industry, from distortion during the machining of extruded shapes of some of the heat-treated aluminum alloys. In some cases, the distortion was so severe that the shape was unsuitable for the intended use. An investigation was therefore conducted on the aluminum alloys 14S-T6, 61S-T6, and 75S-T6 to evaluate various methods of reducing the residual stresses which were thought to be the cause. The effect on residual stresses of quenching rate from the solution heat-treating temperature was investigated for the following quenching media:

cold water, cold water spray, boiling water, light oil at temperatures ranging from 70° to 264°F, and an air blast. Different degrees of stretching before artificial aging and reheating treatments after aging were also evaluated.

Since this investigation was concerned principally with deformation during the machining operation, no attempt was made to determine the residual stresses quantitatively. Instead, a procedure was developed which permitted the direct measurement of the distortion of specimens (a complex extruded shape 10 in. in length) resulting from a longitudinal saw cut. All samples were subjected to the same sequence of saw cuts, and the average deformation of several cuts on several specimens was used to measure the tendency to distort during machining.

The type of quench was found to be highly important, with the boiling water quench best and the cold water quench the poorest from the standpoint of distortion. Unfortunately, however, the boiling water quench, because of section size involved, appreciably lowered the mechanical properties of the alloy. Stretching the product was found to be generally effective in reducing the distortion, but stretching alone was in no case sufficient. Reheating

Fig. 14—Relationship of yield and tensile strength (-T4 condition) and maximum residual longitudinal tensile stress in cylinders, 3.0x9.0 in., of various aluminum casting alloys quenched from the respective commercial heat-treating temperatures in water at 70°F.

the product after artificial aging, in the range where the tensile properties would not be seriously impaired, did not significantly decrease the distortion.

After an appraisal of the results of this investigation and considerable experimental work in the fabricating plants, a special metallurgical technique was devised which resulted in sufficiently uniform mechanical properties throughout the cross section so that a controlled stretching operation gave an acceptably low degree of distortion during machining without affecting the final strength of the product. The temper produced by this process is known as -T64 and it applies only to alloy 14S extruded shapes. This product can be used with the assurance that machining operations will not produce any serious distortion.

The cylinder muff and the extruded shape problems illustrate applications where rather high residual stresses were responsible for distortion or change in dimensions of the part during machining. The extent of warpage resulting from residual stresses is also influenced by the design or size of the part. Important factors are a large variation in sectional thickness or high ratio of width to length dimensions and the character and sequence of the machining

Fig. 15—Effect of quenching rate on the magnitude of the residual stresses in alloy 142 airplane cylinder muffs, 8.5x5.5 in., quenched from 960°F in water at 90° and 212°F and subsequently stress relieved 9 hr at 525°F.

operations. In such instances, intermediate straightening may be necessary, and it is preferable to avoid machining to finished dimensions from one side only. An attempt should be made to balance the machining operations, leaving sufficient allowance to compensate for any final straightening found necessary. However, the residual stress level may be relatively low, but nevertheless substantial warpage may occur during machining or on removal of the part from the clamping device as the result of improper tools or machining practices.

In addition to residual stresses, there are several other sources of distortion or change of dimensions during machining. Careful consideration should be given to cooling the part during machining operations if precise dimensions are to be attained. Aluminum alloys have a high coefficient of thermal expansion, and therefore adequate cooling practices should be employed.

An important cause of distortion in many machining operations is improper jiggling or chucking of the part, so that it is elastically deformed or sometimes even stressed beyond the yield strength. Since a good mechanic would adequately tighten the clamps that hold the part during the machining operation, the fixture should be so designed that such tightening does not deform the part. Very high stresses can be produced by improperly designed fixtures, and the stresses may be redistributed in subsequent machining operations. If the part is overheated during machining, the yield strength is reduced by the temperature and, furthermore, the strains imposed by the fixture may be higher. The distortion occurs during machining or upon removing the part from the fixture. Considerable experience in the field has indicated that more distortion or warpage in cast aluminum alloy parts and some forgings has resulted from this cause than from any of the other sources.

Distortion or change in dimensions of parts as the result of permanent growth in aluminum alloys is thought by some to occur at room temperature or on reheating to temperatures up to 300°F. Growth is caused by an advanced stage of precipitation of constituents in the alloy, and definitely does not occur at room temperature. In fact, extensive tests have demonstrated that no significant changes in dimensions have been detected in aluminum alloys from growth, at room temperature or at slightly elevated temperatures. Therefore, the tendency to

grow is not a source of change in dimensions during machining or in subsequent storage.

Stress Corrosion Cracking: High residual stresses are known to be an important contributing factor in the phenomenon of stress corrosion cracking. Several applications were previously described where the presence of excessive residual stresses contributed to premature cracking or failure of the part in corrosive or natural environments. An interesting example of a quantitative stress analysis, that revealed high residual stresses promoting stress corrosion cracking, will be discussed.

An unusual type of failure was encountered in the early use of Alcoa 76S, an aluminum-zinc-magnesium forging alloy, for aircraft propeller blades of high strength and hardness with improved abrasion resistance. The propeller blade, having about a 6.0 in. diam shank, was forged solid, solution heat-treated, and artificially aged. Then a tapered hole about 17 in. in length was bored in the center of the shank with the diameter gradually decreasing from about 3.0 in. at the end of the shank as illustrated⁵ in Fig. 16. Large cracks occurred during service and were detected when oil from the variable pitch propeller mechanism leaked through the oil-retaining

Fig. 16—Stress corrosion fracture (within the dotted lines) of shank of a forged alloy 76S propeller, caused by high residual tensile stresses in surface layers of bored hole resulting from rapid quenching from 860°F. E. H. Dix, Jr.⁶

Fig. 17—Effect of quenching rate on the magnitude of the residual stresses in alloy 76S propeller hubs, 4.0 in. diameter x 4.0 in. long, quenched from 860°F in water at various temperatures.

ring into the bore. A crack and the stress corrosion fracture (within dotted lines) are shown in Fig. 16. An investigation revealed that the central portion of the original propeller hub contained high tensile stresses produced by the rapid quenching from the solution heat-treating temperature of 860°F in water at 150°F. The machining of the bore exposed layers at the surface of the hole having high circumferential tensile stresses.

Analysis of residual stresses in sections from alloy 76S propeller hubs, 4.0 in. diameter x 4.0 in. long, quenched from 860°F in warm water at 150° or 168°F and in boiling water revealed that the first two quenches produced a relatively high level of stress, whereas the boiling water quench resulted in low tensile stresses in the center, Fig. 17. Fortunately, alloy 76S is comparatively insensitive to the rate of quenching, and satisfactory mechanical properties can be obtained with the less drastic boiling water quench. This investigation resulted in the commercial adoption of a boiling water quench. As an additional precaution, the propeller manufacturer shot-peened the surface of the drilled bore. The shot peening reduced any possibility of a high interior surface tensile stress and may have imposed a compressive stress. After the introduction of the two procedures, no stress corrosion cracking was experi-

enced, and hundreds of thousands of 76S-T61 propeller blades have been in successful service, beginning in 1942.

Relief of Residual Stress by Thermal Treatments

To insure proper selection of conditions for obtaining optimum combinations of mechanical properties, resistance to corrosion, volumetric stability, and freedom from residual stress problems in heat-treated aluminum alloys, it is desirable to acquire data on the effect of time and temperature on the rate of relief of residual stress. The magnitude of the residual stress can be reduced to a satisfactorily low level by reheating to a temperature at which sufficient plastic flow can occur. However, such stress-reducing methods are not practical in all cases because of the sacrifice in other important engineering properties.

It is recognized that the relief of residual stress involves the phenomenon of flow or creep. Creep characteristics, however, ordinarily are determined by measurement of rate of deformation at constant stress. The relief of residual stress is concerned with flow conditions at relatively constant deformation and decreasing stress. Flow under these conditions is sometimes referred to as relaxation. Relatively little investigational work has been done in this field. There are some indications of a quantitative relationship between relaxation and creep, but the data available at the present time are too meager to permit the definition of any correlation.

The Sachs boring-out method of stress analysis can be applied to the determination of the rates of relief of residual stress in metals. Thus, Kempf and Van Horn³⁵ presented curves showing the rate of stress relief in heat-treated solid cylinders of alloy 122 and in 52S-H34 drawn tubes for several reheating periods at a specific temperature. The curve for the tubes is reproduced in Fig. 18. Both stress-relief curves revealed that the initial reheating resulted in a rapid decrease of 25 to 50 pct of the original[‡] re-

‡ The original maximum residual stress was about 47,500 psi tension in the 122 alloy cylinders and 15,650 psi tension in the 52S-H34 tubes. Subsequent tests demonstrated that the time required to relieve a certain percentage of the residual stress at a specific temperature was independent of the magnitude of the original stress.

Fig. 18—Relief of stress at 300°F in 52S-H34 drawn tubes and externally loaded 52S-H34 beam specimens, original stresses 15,650 and 27,000 psi, respectively. Tubes 2.75 in. ID, 3.75 in. OD, 6.0 in. long. Beams, 0.25x0.06x12.0 in. Kempf and Van Horn.³⁵

sidual stress, and that further reduction occurred much more slowly on extended heating. In general, the higher the temperature of reheating, the greater the initial reduction in stress and the greater the rate of subsequent relief. It is important to observe that these stress-relief curves resemble the relaxation curves reported in the literature.^{86, 87} This immediately suggests that a measurement of the relaxation characteristics might be a convenient and more economical means than the Sachs method for determining rates of relief of residual stress in metals. Obviously, the Sachs method would require the careful boring and measurement of a large number of cylinders representing many different periods of heating at various temperatures for all the aluminum alloys. However, the quantitative determination of rates of relaxation is by no means simple, involving as it does the accurate measurement of a varying stress under conditions of relatively constant deformation; also determinations must usually be made at elevated temperatures.

Kempf and Van Horn³⁵ considered it sufficient to determine at room temperature the variations in stress, with time at elevated temperature, of specimens maintained during the entire operation at a constant deformation. To achieve this end, a fixture

was utilized that was developed by Dr. W. L. Fink. The fixture⁸⁵ consisted merely of a means for maintaining a small beam of rectangular cross section under constant deformation during reheating, the remaining stress to be measured subsequently at room temperature. Many measurements for different periods of time at a specific temperature can easily be obtained on the same specimen. These tests can be continued until the desired relaxation of stress is achieved. Thus, it is possible to determine the rate of stress relief in a relatively inexpensive manner for different temperatures and periods of time, and for various amounts of imposed stress. Fig. 19, reproduced from this investigation,⁸⁵ illustrates data obtained for the relief of several imposed stresses in alloy 122 beams at 435°F for various time periods. Data for several aluminum casting alloys heated at different temperatures were also included in this paper.

Similar stress-relief surveys can be obtained for any metal. Thus, Fig. 20 from Stewart⁸⁸ represents the effect of tempering temperature on carbon steel

Fig. 19—Relief of stress in beam specimens, 0.25x0.06x12.0 in., of alloy 122 at 435°F. Curves show stress-time relationship for different original loads indicated. All specimens air-cooled from 930°F. Kempf and Van Horn.⁸⁵

boiler plate prestressed in tension to 25,000 psi for various periods of time. In Fig. 20, the stress was constant, while in Fig. 19 the temperature of stress relief was the same for different imposed stresses.

A comparison of the results of the relaxation procedure with those of the Sachs method for determining the rate of stress relief is also shown in Fig. 18. Beam specimens were prepared from 52S-H34 sheet, stressed to about 27,000 psi and reheated for various periods of time at 300°F. The results are represented by open circles in Fig. 18. The curve for the rate of relief of residual stress in hard-drawn 52S-H34 tubes (stress 15,650 psi), determined by the Sachs method, is included in Fig. 18. The resemblance between the two curves is apparent, and undoubtedly is a result of essentially linear distribution of stress in the wall of the tube and, of course, in the stressed beam. Apparently a relationship exists between the rate of relief of residual stresses produced in the cold drawing of the tube and of the stresses imposed by external means in the beam method.

An even better correlation between the Sachs and beam methods for the determination of the rates of stress relief was obtained for alloy 14S. In this case, the residual stresses were produced by quenching

Fig. 20—Relief of stress in 0.5 in. diameter carbon steel specimens of boiler plate prestressed to yield (25,000 psi) before tempering. Curves illustrate stress-time relationship for different tempering temperatures. Stewart.⁸⁸

rather than by mechanical means. These stresses were relieved, measured, and compared with similar stress values in beams imposed by external loads. Fig. 21 shows the results for solid cylinders of 14S quenched from 940°F in water at 150°F and beams stressed to 24,600 psi. The maximum residual longitudinal tensile stress in the quenched 14S cylinders was the same, 24,600 psi. Both cylinders and beams were heated at 437° and 500°F for different periods of time. It was concluded that the beam method should have some utility in arriving at qualitative data for selecting optimum aging or annealing treatments for the various cast and wrought alloys.

Stress-time measurements have now been completed by the beam method for the majority of the cast and wrought aluminum alloys. The amount of stress relief was determined for initially applied stresses of 4,000, 7,000, 10,000 and 14,000 psi at various temperatures, depending on the alloy, for time intervals of minutes up to 100 hr. A typical example of the results for all the original stresses is represented in Fig. 22, including a number of cast and wrought alloys heat-treated at the respective commercial temperatures, quenched in boiling water, and reheated at 482°F, for different time periods. The alloys exhibited different rates of stress relief, showing that composition has an important effect.

In all cases, an appreciable proportion of the stress relief occurred during the first hour of heating. The higher the temperature the greater was the rate of stress relief, both during the initial and subsequent

Fig. 21—Stress relief at 437° and 500°F for alloy 14S cylinders, 3.0x9.0 in., and beam specimens, 0.25x0.06x12.0 in., quenched from 940°F in water at 150°F. Maximum residual longitudinal tensile stress in quenched cylinders 24,600 psi and original tensile stress in beams 24,600 psi.

Fig. 22—Relief of stress in beam specimens of various cast and wrought aluminum alloys at 482°F. Original stresses were 4,000, 7,000, 10,000, and 14,000 psi. Beams 0.25x0.06x12.0 in., quenched from the respective commercial heat-treating temperatures of the alloys in boiling water.

heating periods. The stress-time data obtained at the various temperatures for all the alloys demonstrated that in order to obtain a low level of residual stress by relaxation heat treatments, the temperature is more important than the time factor. The effect of temperature on the relaxation rate of three aluminum alloys for a 10-hr heating period is illustrated in Fig. 23. The higher the initial stress, the more rapid was the rate of relief in terms of actual stress. However, the time required to relieve a certain percentage of the residual stress at a specific temperature was independent of the magnitude of the initial stress.

The rate of stress relief varied considerably with the different cast and wrought alloys. The rate of relief was relatively rapid with the essentially binary aluminum-copper and aluminum-magnesium alloys (122, 195, and 220) and with alloys 14S, 25S, 75S, 32S, A132, and 356. The slowest relaxation rates were exhibited by alloys 18S, B18S, 76S, and 142. The very slow rates of relaxation of alloys 18S, B18S, and 142 seemed to indicate that the alloys possessing a high strength at elevated temperatures would also have a slow rate of stress relief. However, this is not always true, because alloys 14S and 122 have rapid relaxation rates.

The close agreement between the stress-relief rates of the wrought alloy 32S and cast A132 of similar composition, and of wrought B18S and cast

Fig. 23—Effect of reheating temperature on the rate of stress relief in 10 hr of alloy 142, 355, and A51S beam specimens. Beams, 0.25x0.06x12.0 in., were quenched from the commercial heat-treating temperatures into boiling water and stressed 4,000, 7,000, 10,000, and 14,000 psi.

alloy 142 of the same analysis, indicated that the rate of relaxation is not affected by the type of microstructure or the method of fabrication.

It was thought that a correlation should exist between the relaxation rates and the high temperature creep values for the various aluminum alloys. However, from the limited creep data now available it appears doubtful that such a relation can be established.

The effectiveness of the commercial artificial aging treatments in relieving a substantial percentage of the residual stress depends on the rate of relaxation of the specific alloy. If the alloy is one that exhibits a rapid rate of stress relief, a relatively large percentage of the stress will be released, al-

Fig. 24—Relationship of maximum residual longitudinal compressive stress to typical yield strength for aluminum forging alloys in various commercial tempers. Data for 3.0x9.0 in. cylinders.

though the aging temperature may be as low as 300° to 400°F. However, if the alloy is one that has a slow relaxation rate, the low temperature generally employed for aging treatments will relieve only a small percentage of the residual stress.

Residual Stresses in Various Aluminum Alloys With Different Commercial Heat Treatments: The effects of quenching rate, quenching temperature, section size, and alloy composition on the residual stresses resulting from quenching various commercial wrought and cast aluminum alloys have been described. The progressive boring method of Sachs was employed to determine the magnitude and distribution of the stresses. Only a limited number of residual stress determinations were made on cylinders which had been given commercial heat treatments involving aging at elevated temperatures subsequent to quenching because of the expense and time involved in the Sachs method.

It was considered desirable to compile the relative magnitudes of the stresses which could be expected in the various alloys in their respective commercial tempers, the effects of all other factors such as section size remaining constant. Fortunately, cylinders of a standard size were employed for a large proportion of the program. In order to obtain such data, it was necessary to combine the results of the stress determinations on as-quenched cylinders with information on the percentage of stress relief effected by the various aging treatments. The latter information on the rates of stress relief of cast and wrought aluminum alloys was described in the previous section. Rates of stress relief determined by the relaxation beam method were com-

pared with rates measured by the Sachs analysis and found to be identical, Figs. 18 and 21. Thus, the combination of the information obtained by the two experimental methods should provide valid data for determining the stresses present after complete heat treatment.

In some cases results were available for 3.0x9.0 in. cylinders which had been subjected to a commercial heat treatment and artificial aging before stress analysis. Values obtained from such measurements were, of course, valuable and served as a confirmation of the procedure adopted.

The primary objective of this work was to provide data on the comparative residual stresses which

Fig. 25—Relationship of maximum residual longitudinal compressive stress to typical yield strength for aluminum permanent mold alloys in various commercial tempers. Data for 3.0x9.0 in. cylinders.

might prevail in commercial forgings or castings after complete heat treatment. The data revealed differences between alloys as well as between various tempers of a specific alloy. It was apparent from the results that the stresses developed in actual forged or cast parts are affected to a considerable degree by the section size and geometry of the part. However, the results should permit valid conclusions concerning the relative stresses in parts of equivalent size and shape in different alloys and tempers.

Probably the greatest value of such information is its application to the problem of distortion on machining. The character of the stress state, involving triaxial stresses and some variations in the distributions of the three stresses, is so complex that no simple relations have been discovered between the anticipated distortion for a certain machining operation and any of the calculated or measured maximum stress values. However, if a casting or forging of large size were to be bored so that the hole diameter were relatively small in proportion to the external dimensions of the piece, it is probable that the amount of distortion per inch would be approximately proportional to the magnitude of the tensile stresses at the center of the section. The distortion in this case would be expressed by an expansion in the external dimensions. However, if the machining operations removed stock from the surface, the distortion would appear as a contraction, and the relative amount of the contraction would be related to the magnitude and distribution of the surface compressive stresses. Difficulties arising from the release of residual stresses are frequently encountered in slotting. In such operations

the magnitude of stresses in both the surface and center layers would be of importance. The commonest manifestation of these changes is the bending or warping of the part.

Maximum longitudinal compressive stresses in various tempers of the forging alloys ranged from 1,600 psi for 14S-T61 to 24,500 psi for 14S-T4, other alloys and tempers investigated having intermediate values. Similar stresses in casting alloys varied from 200 psi for 195-T7 to 6,800 psi for 355-T4. Among the factors affecting the level of residual stresses in heat-treated parts, the quenching rate was indicated to have an influence considerably greater than that of the alloy composition or the elevated temperature aging treatment, and in all cases a heat-treating practice which involved quenching in boiling water produced a much greater reduction in residual stresses than in the tensile properties. Thus, for example, the residual stresses in alloy 14S varied by a ratio of 12 to 1 or more, depending upon whether the quenching water was at 150° or 212°F. Decrease in the magnitude of the residual stresses with elevated temperature aging treatments of the -T6 type varied from 7 to 44 pct among the various forging alloys.

Fig. 26—Relationship of maximum residual longitudinal compressive stress to typical yield strength for aluminum sand casting alloys in various commercial tempers. Data for 3.0x9.0 in. cylinders.

In general, the magnitude of the residual stresses in casting alloys was lower than in forging alloys, because of the prevalence of boiling water quenching for casting alloys. As a result, less variation was encountered among the different casting alloys than among forging alloys in commercial tempers. The percentage of stress relief effected by the elevated temperature aging portions of the -T6 heat treatments varied from 3 pct for casting alloy 355-T6 to 30 pct for 355-T62. The aging cycle of the -T7 type treatments provided stress-relief values of from 43 pct for casting alloy 355-T7 to 96 pct for 195-T7. With the substantial reductions in the magnitude of the residual stresses provided by -T7 type treatments, measurable improvements with respect to distortion on machining can be expected. Generally the most favorable combinations of tensile properties and residual stress values were provided by a low quenching rate followed by artificial aging to the -T6 temper.

Engineers responsible for the design of parts and the selection of suitable alloys and tempers are concerned with relations between the anticipated re-

Fig. 27—Machined alloy 75S-T6 test specimen representing the integrally stiffened structure of the Lockheed Super Constellation airplane. Specimen was not stretched after quenching.

sidial surface stresses and the fatigue characteristics of the parts. In some cases the allowable range for fatigue stresses applied in service is restricted by the presence of residual stresses developed in the heat-treating operation.

Consequently, various commercial tempers have been developed for aluminum alloys with the primary objective of fabricating products having a low level of residual stress. These tempers usually do not represent maximum strength properties, but the reduction is modest, considering the degree to which residual stress problems are eliminated. It is, of course, necessary to establish the relation between the typical strength properties of the different tempers of the various alloys and the associated residual stresses. It was decided to express the maximum longitudinal residual compressive stress as a percentage of the typical yield strength. In the case of forging alloys, the longitudinal compressive stress ranged from about 3 pct to as high as 61 pct of the yield strength. This relationship depended not only on the severity of the quench, but also to an appreciable degree on the effects of elevated temperature aging, since a considerable change in yield strength values accompanies the aging treatments.

The relation between the maximum longitudinal residual compressive stress values and the typical yield strengths for the forging alloys is illustrated in Fig. 24. It was apparent that the value of the maximum longitudinal compressive stress in alloys receiving a quench in cold or warm water amounted to 30 to 40 pct of the typical yield strength of the fully hardened temper (-T6 type). When boiling water quenches were employed, the residual stress values were less than 10 pct of the typical yield strengths.

It is of interest that the maximum tangential residual compressive stress was indicated, by the available data from the cast and wrought cylinders, to be approximately equal to the maximum longitudinal compressive stress. Thus, the ratio of the maximum longitudinal compressive stress to the maximum tangential compressive stress varied from 0.79 to 1.21, and the average of this ratio was 0.98. Therefore, the values shown graphically in Fig. 24

can be considered to represent the tangential as well as the longitudinal residual surface stresses. For many purposes the surface longitudinal compressive stresses are undoubtedly the most important; and this consideration, along with the fact that the surface stresses are probably established with greater accuracy and apply to the greatest incremental volume of any cast or forged parts to be machined, was the reason for the selection of the maximum longitudinal compressive stress as providing the most significant data.

The relation of maximum longitudinal residual compressive stresses to the typical yield strengths of various permanent mold casting alloys and tempers is represented in Fig. 25. Similar data for sand casting alloys are presented in Fig. 26.

Relief of Residual Stress by Mechanical Treatments

Mechanical treatments have been used for many years to relieve or realign residual stresses in commercial metal products such as sheet, plate, tube, extrusions, rod, and bar. The mechanical operations employed are stretching, repeated bending, and coining. Stretchers up to 3,000,000 lb capacity, roller levelers, and various other types of roll straightening devices, gag presses, etc. are widely used throughout the metal industry, not only for straightening and forming metal products, but also for reducing the magnitude or improving the distribution of residual stresses in these products. Forgings are often straightened cold in the die.

The mechanism by which the various mechanical treatments reduce residual stresses is perhaps best illustrated by the stretching procedure. Consider a long length of extruded shape in which the outside fibers have a high longitudinal residual compressive stress and the interior layers a correspondingly high longitudinal tensile stress. When the ends of this piece are gripped and the entire piece stretched beyond the elastic range of the alloy, the inner fibers begin to take a permanent set first, because the superimposed tensile stress is added to the residual tension already present. As the stretching force is increased further, the exterior fibers finally begin to assume permanent set, so that the entire cross

section becomes stressed well beyond the limit of elastic action. When the stretching force is removed, both the outer and inner fibers recover nearly the same amount. However, the plastic flow of metal is greater in the interior fibers than in the exterior layers, so that after removal of the stretching force only a small fraction of the initial difference in the residual stresses remains between the inner and outer fibers. One factor controlling the degree of this final difference is the amount of plastic action imposed during the stretching operation. Fortunately, the initial plastic action in such a treatment is more effective than the later stages of plastic flow, so that it is unnecessary to stretch to so high a degree of permanent set that fracture of the piece during the stretching operation might be imminent. Again, fortunately, the amount of stretch required to satisfactorily straighten a part is almost enough to adequately release the residual stresses, and so the minimum required for straightening, or slightly more than this, is the usual amount applied in commercial stretching operations.

The effectiveness of stretching in relieving residual stresses depends also on the uniformity of the mechanical properties, especially yield strength, of the alloy product being stretched. If the cross section is not initially uniform in mechanical properties, stretching can actually produce residual stresses in an otherwise stress-free piece. Of course, the stresses so formed are usually of a smaller magnitude than those produced by quenching in cold water, so that the net effect of stretching is beneficial, even though some minor differences exist in mechanical properties across the cross section. Nevertheless the maximum benefits in relieving residual stresses by stretching can be attained only in a material which has substantially uniform mechanical properties across the cross section.

Tests have repeatedly demonstrated the beneficial effect of stretching on the relief of residual stresses. In one investigation, for example, 75S-T6 extruded shapes after stretching showed only 10 pct as much

warping on machining as was characteristic before stretching. In another test, illustrated in Fig. 27, a 75S-T6 specimen representing the integrally stiffened structure on the Lockheed Super Constellation was machined without having been stretched after quenching. The distortion of the specimen is apparent on the inspection surface plate. In contrast, Fig. 28 reveals the flatness of a similar machined specimen that was stretched between quenching and artificial aging.

Stretching operations are used commercially today on many aluminum alloy products covering a wide range of sizes. Spar chords for airplanes provide another example of aluminum alloy products straightened by stretching after heat treatment that show greatly reduced warpage on machining because the residual stresses have been largely eliminated. Airplane spar chord sections with a cross section of 60 sq in. can be successfully stretched. Very satisfactory results both as to straightness and freedom from warpage on machining have been obtained by such mechanical treatments in many commercial applications.

Relief of Residual Stresses by Combinations Of Thermal and Mechanical Treatments

Mechanical treatments followed by a thermal stress relief are frequently employed to obtain the desired combination of mechanical properties and reduction in residual stresses. An example is the flattening procedure applied to magnesium-base alloy sheet, where a combination of dead load and thermal treatment was used to produce flat, stress-free sheet. Another application is the relatively new method being used by North American Aviation Co. for simultaneously forming, quenching, and stretching high strength aluminum alloy parts by a die quenching process.

Closure

Two objectives have been reached in this exploration of the field of residual stresses in metals. Both the beneficial and the injurious effects of these

Fig. 28—Machined alloy 75S-T6 test specimen representing the integrally stiffened structure of the Lockheed Super Constellation airplane. Specimen was stretched after quenching but before artificial aging.

stresses have been presented in a qualitative and quantitative manner. Numerous examples from commercial experience illustrate the location of these residual stresses and the practical effects which they introduce. Much experimental work remains to be done in this field, however, and it is hoped that this report will provide a useful background of information which will stimulate others to acquire more of the fundamental knowledge necessary for the control of these forces.

Acknowledgment

Tristage Crystallization Process For Utilizing Western Ferrophosphorus

by Lloyd H. Banning, Wallace E. Anable, and R. T. C. Rasmussen

In the rapidly growing industry of elemental-phosphorus production from western phosphates, most of the vanadium and chromium contained in the phosphate rock collect in the byproduct ferrophosphorus. Results are presented of a completed laboratory project, which developed a tristage crystallization and hydrolysis process for recovering strategic vanadium and chromium, as well as a valuable phosphorus product, after extracting these elements from the ferrophosphorus by roasting and leaching.

THE Phosphoria formation in Idaho, Montana, Wyoming, and Utah contains the Nation's largest reserve of phosphate rock. A unique feature of the Phosphoria beds is their content of a fraction of a percentage each of vanadium, chromium, nickel, and molybdenum. Vanadium is the most important as to quantity and value.

Small-scale tests by the Bureau of Mines at Albany, Oregon, in 1947, indicated that most of the vanadium in the phosphate rock collects in the ferrophosphorus product of smelting. Subsequent electric smelting operations to produce elemental phosphorus from western phosphate rock (experimentally by TVA and industrially at Pocatello, Idaho) have shown that the vanadium and other metals in the rock are to a large extent recovered in concentrated form in the ferrophosphorus byproduct.

This paper reports the results of completed laboratory research on the recovery of vanadium from ferrophosphorus, which was undertaken by the Bureau of Mines at Albany in 1948 as the first phase of a project entitled, "Vanadium and Fluorine from Western Phosphates." The various vanadium-recovery methods investigated, including the roast-leach method that showed most promise and was studied in greatest detail, are discussed in an earlier publication.¹ Subsequent systematic study of the roast-leach method of extracting vanadium from western ferrophosphorus developed the more effi-

Westvaco B	5.2	24.7	58.5	5.2	1.0

cient tristage crystallization process, which is the subject of this paper.

Process Development

The investigations were made on ferrophosphorus produced in the electric smelting of elemental phosphorus from western phosphate rock. The TVA provided two sample lots of ferrophosphorus produced in pilot plant smelting of phosphatic shale from the Fort Hall Indian Reservation in Idaho. The Westvaco Chemical Div. of the Food Machinery & Chemical Corp. supplied two sample lots of ferrophosphorus produced by its phosphorus smelter at Pocatello, Idaho. The analyses of all four lots are shown in Table I. Westvaco lot B was the starting material for the more recent tests.

The roast-leach process for recovering vanadium from western ferrophosphorus, as originally developed, employed the following principal steps: Roasting of a mixture of pulverized ferrophosphorus, soda ash, and salt; extraction of the water-soluble vanadium, phosphorus, and chromium compounds from the calcine by leaching, settling, and decantation of the pregnant solution; primary crystallization of trisodium phosphate from the pregnant solution; purification of the trisodium phosphate crystals by dissolution in water and secondary crystallization; purification of the pregnant vanadium solution from the primary crystallization step by adding calcium chloride to precipitate calcium phosphate; and hydrolysis of vanadium red cake from the puri-

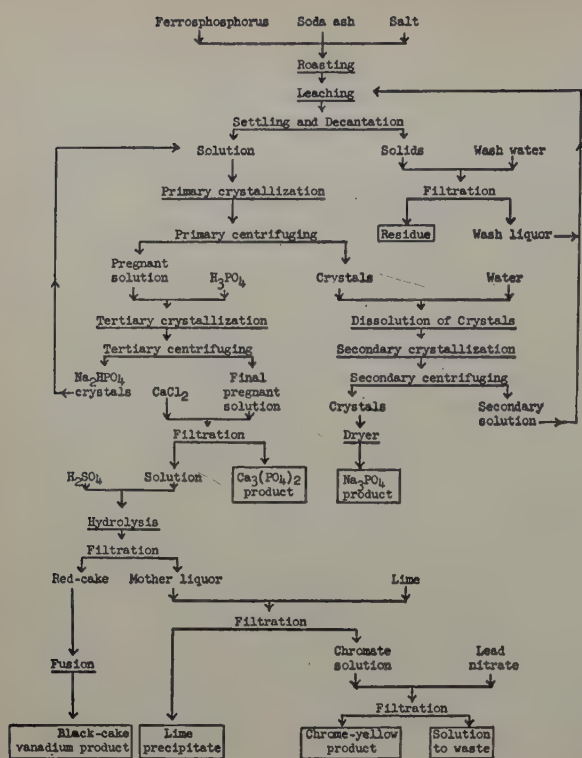

Fig. 1—Flowsheet of tristage crystallization process for recovering vanadium, phosphorus, and chromium products from western ferrophosphorus.

fied pregnant solution. It was recognized that more detailed and systematic study of the several unit operations was desirable, particularly with respect to making a more complete separation of phosphorus from vanadium-bearing solution by crystallization. Methods of recovering chromium remaining in solution after hydrolyzing vanadium also needed to be investigated.

The tristage crystallization process developed in subsequent research is illustrated by the flowsheet of Fig. 1. It differs from the original roast-leach process principally by the addition of a tertiary crystallization step to remove much of the phosphorus remaining in the pregnant vanadium solution from the primary crystallization step. Instead of crystallizing trisodium phosphate, as in the primary and secondary crystallizations, disodium phosphate is brought down by addition of phosphoric acid to the solution before cooling for the tertiary crystallization. This step brings the phosphorus content of the pregnant vanadium solution to a much lower figure than was previously obtainable and also permits recovery of a larger proportion of the phosphorus in a high-purity sodium phosphate product.

As shown on the flowsheet, the more recent studies included tests on conversion of the red-cake product to black-cake and developed one method of recovering chromium as a marketable compound. A more detailed study also was made of the controlling variables in other steps of the process.

Each of the several unit operations comprising the tristage crystallization process will be described individually.

Roasting of Ferrophosphorus with Soda Ash and Salt: The object of roasting is to oxidize the metallic ferrophosphorus and form water-soluble vanadium, phosphorus, and chromium compounds, while avoiding formation of soluble iron compounds. Roasting variables investigated were: soda ash-ferrophos-

phorus ratio, salt-ferrophosphorus ratio, fineness of the ferrophosphorus, temperature, time, degree of oxidation, and amount of rabbling. Most of the roasting tests were carried out in a small rotary kiln.

The optimum quantity of soda ash in the roasting charge was found to be approximately the sum of the quantities theoretically required to react with phosphorus to form trisodium phosphate (Na_3PO_4), with vanadium to form sodium metavanadate (NaVO_3), and with chromium to form sodium chromate (Na_2CrO_4). A satisfactory ratio of dry soda ash to Westvaco ferrophosphorus was 1.45:1. A small quantity of salt (NaCl) in the roasting charge was beneficial, but an excess of salt caused the charge to become plastic below the optimum roasting temperature and resulted in mechanical difficulties. One part of salt to 10 parts of Westvaco ferrophosphorus gave satisfactory results.

Grinding of the ferrophosphorus to -35-mesh provided roaster feed of optimum particle size. Finer grinding accelerated the roasting reaction but increased dust losses, whereas coarser grinding resulted in a less soluble calcine.

The related roasting variables of temperature, time, degree of oxidation, and amount of rabbling must be balanced to obtain calcine having good leaching characteristics, and their control depends to a large extent upon the type of roaster employed. The preferred maximum roasting temperature in the small rotary kiln was between 780° and 800°C . At higher temperatures the charge became plastic, resulting in the formation of nodules that were not properly calcined throughout. The best leach extractions were obtained from calcine that was in the hot zone of the furnace for about 2 hr. Enough oxidation must be attained to produce pentavalent vanadium and phosphorus and hexavalent chromium. Excessive oxidation apparently produces water-soluble sodium ferrate, which causes difficulties in subsequent leaching and crystallization. The degree of oxidation is a function of the roaster atmosphere and of gas-solids contact produced by rabbling, or by tumbling in the rotary kiln, for a given time at roasting temperature.

The best combination of roasting conditions attained in the rotary kiln tests produced calcine in which 95 pct each of the vanadium and phosphorus, 70 pct of the chromium, and virtually none of the iron in the ferrophosphorus were rendered water-soluble.

Leaching of Calcine and Separation of Dissolved Values from Residue: In the early batch leaching tests 500 g of calcine was ground for 5 min in a laboratory ball mill with 2 liters of secondary solution from a previous test. The ground pulp was transferred to a leaching vessel and gently boiled with agitation for 1 hr. After leaching, the solids were settled at a temperature high enough to prevent crystallization. The solution usually was clear enough to decant after settling for 3 hr. The decanted primary solution was sent to the primary crystallization step, while the solids were repulped with water, releached, filtered, washed, dried, and sampled for analysis. The filtrate and washings were combined with the secondary solution from the secondary crystallization step of the process for use in leaching the next batch of calcine.

Later investigations revealed that it was not necessary to grind the calcine before leaching. The procedure subsequently used in simultaneous roasting and leaching tests was to discharge calcine from

the kiln directly into a vigorously agitated boiling leach solution. The specific gravity of the pulp in the leaching vessel was adjusted by frequent small additions of water and recycled solution. When the leaching vessel became full, part of the pulp was removed and filtered.

Occasionally iron was present in the clarified leach solutions in high enough concentration to precipitate during crystallization and discolor the sodium phosphate product. Furthermore, high iron concentration appeared to retard crystallization. The clarified leach solution was acceptably low in iron when the following conditions were met: The solution was alkaline enough so that trisodium phosphate crystals formed on cooling, the pulp was kept vigorously boiling during the leaching operation, the specific gravity of the pulp was kept below 1.27, and the calcine was leached for at least 1 hr.

The leach pulp was kept above the crystallization temperature of trisodium phosphate, which is a function of the phosphorus concentration, until the solution and solids were separated. No trouble was experienced with sodium phosphate crystallizing from solution when the temperature was maintained above 60°C.

Primary Crystallization and Centrifuging: In the primary crystallization and centrifuging operations trisodium phosphate is crystallized and separated from the pregnant solution. The purpose of the step is to make the optimum separation of phosphorus from vanadium and chromium; complete separation cannot be attained as the trisodium phosphate crystals include small amounts of vanadium and chromium, and the remaining solution contains some phosphorus. In the development work on the process a study was made of the relationship between vanadium and phosphorus content of solution and temperature of crystallization. A typical 1500 milliliter sample of primary solution, analyzing 12.1 g V and 54.0 g P per liter, was cooled in the laboratory crystallizer to 20°C and held at this temperature 30 min. A sample of the mother liquor was then drawn from the crystallizer through a submerged fritted glass filter and analyzed for phosphorus and vanadium. The same procedure was repeated for the following temperatures: 15°, 12°, 9°, 6°, 3°, and -3°C. The vanadium and phosphorus analyses and the ratios of vanadium to phosphorus of the mother liquor after each crystallization are shown in Table II.

Results of the crystallization studies indicate that the optimum crystallization temperature for a primary solution containing 12 g of vanadium per liter is between 3° and 6°C, as the vanadium-phosphorus ratio is highest in this temperature range. The relationship between vanadium and phosphorus content of pregnant solution and temperature of crys-

Fig. 2—Effect of crystallization temperature on vanadium and phosphorus content of pregnant solution.

tallization is shown graphically in Fig. 2. It is evident from the graph that the phosphorus content of pregnant solutions decreases linearly as the crystallization temperature is lowered. Conversely, the vanadium content increases to a maximum at about 6°C, then rapidly decreases at lower temperatures. These studies indicate that, if the primary solution were higher in vanadium, the optimum crystallization temperature would be higher, as sodium vanadate would start crystallizing from solution at higher temperature. On the other hand, if the vanadium content were lower, the optimum crystallization temperature would be lower. Hence, the optimum crystallization temperature for a primary solution of known vanadium concentration can be estimated from these data.

Centrifuging has proved superior to filtration for separating crystals from solution, mainly because a drier crystal product can be recovered. In some of the early tests using filtration, the crystals always contained appreciable percentages of vanadium and chromium. By centrifuging, a drier crystal product low in vanadium and chromium was recovered.

Optimum separation of crystals from solution by centrifuging is made only when the minimum crystallization temperature is maintained until the separation is complete. The procedure used in the laboratory test work was to cool the 12-in. basket of the suspended-type centrifuge with ice water before introduction of the crystal-solution mixture. With the basket loaded, the centrifuge was raised to a speed of 3000 rpm. After spinning for 2 min, the crystals were washed with a small amount of ice water, then spun dry in about 1 min.

Purification of Trisodium Phosphate Crystals by Secondary Crystallization: The vanadium and chromium contents of the primary trisodium phosphate crystals vary from 0.1 to 0.2 pct, and the crystals are slightly yellow. To produce a commercial grade of trisodium phosphate the primary crystals must be freed of vanadium and chromium by dissolution in water and recrystallization. Therefore, studies were made to determine optimum conditions for the recrystallization procedure.

A series of eight secondary crystallization tests indicated that a linear relationship exists between

Table II. Effect of Primary Crystallization Temperature on Vanadium and Phosphorus Content of Pregnant Solution

-3	7.0	2.8	2.50

Fig. 3—Effect of crystallization temperature on vanadium and phosphorus content of secondary solution.

the minimum crystallization temperature and the phosphorus content of the secondary solution. The vanadium content of the crystals did not increase at lower crystallization temperatures, as it did in the primary crystallization step. The results of these tests, shown graphically in Fig. 3, indicate that the optimum crystallization temperature is just above the freezing point of the solution.

The effect of phosphorus concentration of solution on the purity of the trisodium phosphate product was investigated in eight recrystallization tests. Solutions with phosphorus concentrations ranging from 27 to 68 g per liter were prepared by dissolving wet primary crystals that contained 0.09 pct V and 6.2 pct P in water. The tests were conducted by cooling 1500 milliliter batches to -1°C and holding at this temperature for 30 min before centrifuging. The crystal products and solutions were measured and analyzed for vanadium and phosphorus. The result of these tests is shown graphically in Fig. 4.

A study of the results of the secondary crystallization tests indicates that under specific conditions a tenfold reduction of the vanadium content of primary crystals can be obtained while recovering 88 pct of the phosphorus in the purified trisodium phosphate crystals and 91 pct of the vanadium in the secondary solution. The graphs also indicate that a choice must be made between high crystal yield and low vanadium content of trisodium phosphate crystals in the secondary crystallization operation. However, low crystal yield in this operation does not necessarily mean low overall phosphorus recovery as the secondary solution is recycled to the leach tank. Only the phosphorus in the residue and in the purified pregnant solution is lost. In plant practice it should be possible to obtain a high overall recovery of phosphorus as trisodium phosphate crystals of low vanadium content.

Purification of Pregnant Solution: When the optimum vanadium-phosphorus separation is made in the primary crystallization and centrifuging operations, the phosphorus content of the pregnant solution is 6 to 8 g per liter. The solution for the vanadium hydrolysis operation must contain no more than about 1 g of phosphorus per liter in order to get a satisfactory recovery of vanadium as red cake

of acceptably low phosphorus content. The conventional procedure for reducing the phosphorus content of pregnant solution is to neutralize with acid and add sufficient calcium ion to precipitate phosphorus as calcium phosphate. The precipitate invariably contains appreciable vanadium and, hence, the more phosphorus that is precipitated from solution as calcium phosphate the lower is the vanadium recovery.

Investigations revealed that disodium phosphate could be crystallized from pregnant solution to the extent that less than 1 g per liter of phosphorus remained in solution. Disodium phosphate was crystallized from pregnant solution by adjusting the pH to 8.8 with phosphoric acid before cooling. Tests have shown that phosphoric acid is the most desirable reagent for the pH adjustment, as the use of other acids introduces foreign ions into the solution which show up in crystals and contaminate the final

Fig. 4—Effect of dilution on the purification of primary crystals.

trisodium phosphate product. To determine the relationship between temperature of crystallization and phosphorus content of pregnant solution, a series of eight tests was made, the results of which are shown graphically in Fig. 5.

When the third crystallization and centrifuging operation is carried out under favorable conditions, the resulting solution may be used directly for hydrolysis. The crystals from these operations are dissolved in the clarified solution from the primary leaching step; and the phosphorus, including that added as phosphoric acid, is recovered in the trisodium phosphate product. If a higher purity vanadium red-cake product is desired, the solution can be further freed of phosphorus by precipitation with calcium ion before hydrolysis.

Recovery of Vanadium by Hydrolysis: Vanadium recovered from ores is usually sold as fused black vanadium oxide. For grade A fused black vanadium oxide (suitable for manufacture of ferrovanadium and special alloys, direct addition to alloy steel, or the manufacturing vanadium chemicals) the Army and Navy Munitions Board specifies a minimum of 86 pct V_2O_5 (48.2 pct V) and a maximum, in percent, of: P, 0.05; S, 0.15; Cu, 0.05; Sb, 0.05; As, 0.05; Ni, 0.10; Pb, 0.15; Zn, 0.15; and insolubles, 1.0. When recovering vanadium from ores, phosphorus is probably the most troublesome impurity to eliminate

Fig. 5—Temperature relationships when crystallizing disodium phosphate.

from the final vanadium product. The ferrophosphorus used in the test work contained from 4 to 5 pct V and 24 to 25 pct P; so the problem of separating phosphorus from the vanadium product was particularly difficult. By the three crystallization and centrifuging operations described in the foregoing, the vanadium-phosphorus ratio was raised to 15 to 1 in the final pregnant solution, and in some tests the pregnant solution contained as little as 1 g of phosphorus per liter. Still more of the phosphorus can be eliminated from solution prior to hydrolysis by neutralization with sulphuric acid and precipitation of phosphorus as calcium phosphate, thereby increasing the vanadium-phosphorus ratio to as high as 60:1. The final separation of vanadium from phosphorus takes place in the hydrolysis operation.

The apparatus in which hydrolysis tests were first successfully carried out consisted of a 3-neck, 1-liter flask, equipped with a reflux condenser, a thermometer, a mechanical stirrer, and a constant level water bath. Later, to simulate plant conditions more closely, a 3-liter stainless steel beaker was substituted for the 3-neck glass flask. Then, in some of the last tests, a 7-liter stainless steel beaker was used. Equally satisfactory recoveries and grades of red-cake product were obtained in the stainless steel beakers as in the all-glass apparatus.

In making the hydrolysis tests, the pH of the solution was adjusted, after which the solution was heated to the desired temperature while being agitated. In most of the tests the solution was heated to the boiling point, and the volume of solution was kept constant by condensing the vapors and returning them to the hydrolysis vessel or by the addition of water. Samples of the solution were checked at frequent intervals for pH and for vanadium content.

Table III. Results of Some Hydrolysis Tests

Test No.	Red-Cake Analysis, Pct			V Yield, Pct
	V	P	Cr	
17	45.4	0.01	0.7	96.2
18	43.8	0.01	1.1	98.1
19	42.4	0.01	0.8	84.4
20	42.9	0.22	0.8	92.8

Note: Spectrographic analysis of red cakes from tests 18 and 20 indicated no impurities over specifications.

Although the hydrolysis of vanadium from solution is a known procedure, some variables of the hydrolysis operation were given careful study. These studies indicated the following trends:

1—The rate of the hydrolysis reaction and the percentage yield are dependent upon the vanadium concentration of the solution.

2—High phosphorus concentration in the hydrolysis solution depresses the reaction rate, lowers the yield, and contaminates the red-cake product.

3—The hydrolysis reaction rate is accelerated by raising the temperature.

4—Small acid additions at intervals of 15 min until the pH is stabilized accelerate the reaction rate.

The manner in which some of the foregoing trends were determined may be graphically illustrated. To study the effect of hydrogen ion concentration (pH)

Fig. 6—Hydrolysis of vanadium solutions.

on hydrolysis rate, two tests were made on identical pregnant solutions containing only 0.2 g of phosphorus per liter. In one test (No. 18), after the initial adjustment of the pH to 3.0, 2 milliliter additions of sulphuric acid were made at 15-min intervals. Thirty minutes after the test was started the pH of the solution had increased to 4.6, but after 2 hr it had dropped to 3.1 and the acid additions were stopped. In another test (No. 19), no acid additions were made after the initial adjustment of the pH to 3.0. After a half hour of operation the pH of the solution had increased to 4.9 and precipitation of vanadium apparently ceased. The results of these tests are plotted in Fig. 6. To illustrate the effect of phosphorus concentration in the solution on the rate and completeness of vanadium yield, the results of tests 17 and 20 are also plotted in Fig. 6. In these tests small acid additions were made frequently as described for test 18. The phosphorus content of the solution in test 17 was 0.6 g per liter, and in test 20, 2.7 g per liter. The analyses of the red-cake products from these tests are shown in Table III.

Red cake is a light, fluffy precipitate, and for most commercial uses fused black vanadium oxide is preferred. Red cake is converted to the fused black form by heating to 800°C and then tapping into a suitable mold. Laboratory tests have indicated that the fused black vanadium oxide is higher in vanadium and lower in phosphorus than the red cake from which it was produced. In a typical test the vanadium

content increased from 45.1 pct in the red cake to 47.9 pct in the black cake and the phosphorus content dropped from 0.15 to 0.029 pct. In another test the vanadium content increased from 41.8 pct in the red cake to 50.2 pct in the black cake. Spectrographic as well as chemical analyses indicated no objectionable quantities of undesirable impurities in the fused, black-cake products.

Recovery of Chromium: After recovery of phosphorus as trisodium phosphate and vanadium as red cake, almost all of the chromium leached from the calcine remains in solution at a concentration of 10 to 14 g per liter. The most promising method investigated for recovering chromium from this solution was precipitation as chrome yellow (lead chromate). The object of the investigation was to determine whether pigment-quality chrome yellow could be recovered. The composition requirements for commercially pure lead chromate pigments, according to the ASTM Specification D211-47, are shown in Table IV.

Before pigment-quality chrome yellow could be recovered from the vanadium hydrolysis filtrate, it was necessary to free the solution of 0.02 to 2.0 g of phosphorus per liter, 0.25 to 1.0 g of vanadium per liter, and some of the excess sulphate radical.

Table IV. Requirements for Composition, Chrome Yellow and Chrome Orange

	Type				
	I	II	III	IV	V
Lead chromate (PbCrO ₄) minimum, pct	50	68	93	60	55
Total matter soluble in water, maximum, pct	1.0	1.0	1.0	1.0	1.0
Total of all substances other than insoluble compounds of lead, maximum, pct	8.0	8.0	7.0	3.0	3.0
Moisture and other volatile matter, maximum, pct	1.0	1.0	1.0	1.0	1.0
Coarse particles, total residue retained on a No. 325 (44-micron) sieve, maximum, pct	1.0	1.0	1.0	1.0	1.0

Lime was used to precipitate these impurities. Upon the addition of lime, phosphorus precipitated first; when enough lime was added to raise the pH of the solution to 10.9, vanadium precipitated. Lime added in excess of that required to precipitate phosphorus and vanadium precipitated the sulphate radical. Part of the sulphate in the solution resulting from the hydrolysis of vanadium may be used to good advantage in the chrome yellow, as it precipitates as insoluble lead sulphate.

The main constituent of the lime precipitation product was calcium sulphate. Tests have indicated that less than 4 pct of the chromium was lost in this product and that excess lime caused no additional loss of chromium.

After the solution was freed of phosphorus, vanadium, and excess sulphate radical, chromium was precipitated as chrome yellow with lead nitrate or lead acetate. The effects of varying lime and lead acetate additions were demonstrated in a series of tests. In some, the lime used to precipitate impurities from solution was varied from 12.5 to 25 g per liter and the theoretical amount of lead acetate was used for precipitating chrome yellow. In others, the lime additions were held constant at 12.5 g per liter and the lead acetate additions were varied from 50 to 150 pct of the theoretical. In still others, the lime additions were held constant at 25 g per liter and the lead acetate additions varied the same as in the second series.

It was assumed that all of the chromium in the chrome yellow precipitate was present as PbCrO₄ and that all of the sulphur was present as CaSO₄. In some tests, the calculated lead chromate added up to over 100 pct. In others the calculated lead chromate plus the calculated calcium sulphate added up to over 100 pct. These results indicate that the assumption as to compounds present may not be altogether correct. Nevertheless, this series of tests shows that, by proper lime control in the precipitation of impurities and subsequent controlled lead acetate additions, it may be possible to produce any type of pigment-quality chrome yellow from the chromium in the hydrolysis filtrate. The results of these tests are shown in Table V.

Simulated Plant Test

The object of this test was to simulate plant operating conditions and to determine the recovery of vanadium, phosphorus, and chromium in finished products under such conditions. The first step in the process, roasting, was done in a small rotary kiln of 8-ft length and 5-in. ID. The kiln was set on a slope of 1/2 in. per ft and rotated 1 1/4 rpm. Temperature in the kiln was automatically controlled between 1430° and 1450°F.

The charge for the test was a mixture of 18 lb of -35-mesh ferrophosphorus, 26.1 lb of soda ash, and 1.8 lb of salt (NaCl). The mixed charge was fed continuously to the kiln. After normal operating conditions were established, the calcine was discharged into agitated pulp in a leaching vessel. The specific gravity of the pulp was maintained between 1.25 and 1.30 by frequent water and solution additions. Heat was applied to the leaching vessel to keep the pulp boiling. When the leaching vessel became full, part of the pulp was removed, filtered, and the filter cake washed with water. The filter cake was then repulped with water and releached. During the two-day operation, seven batches of pulp were processed. The results of the leaching operation are shown in Table VI, and a materials balance for the roasting and leaching operations is shown in Table VII.

Table VI. Results of Continuous Leaching of Calcine

The materials balance indicates that 98.1 pct of the vanadium, 96.0 pct of the phosphorus, and 100 pct of the chromium contained in the materials that went into the test were accounted for in the products. The retention of vanadium, phosphorus, and chromium in the combined kiln and dust-box clean out was high, as the calcine that was discharged from the kiln before normal operating conditions were reached was included in this product. Under continuous operating conditions this loss would be almost negligible. Disregarding the loss in the combined kiln and dust-box clean out, 94.5 pct of the vanadium, 93.9 pct of the phosphorus, and 69.3 pct of the chromium were extracted from the ferrophosphorus. The primary solution contained 91.1 pct of the extracted vanadium, 93.2 pct of the extracted phosphorus, and 95.0 pct of the extracted chromium.

The primary crystallization operation was carried out by cooling 1600 milliliter batches of primary solution to 5°C in a laboratory crystallizer. Four batches were crystallized and stored in a refrigerator, then combined before centrifuging. Four batch centrifuging operations were required to treat all of

the crystallized product. The crystal-solution mixtures were introduced into the centrifuge at temperatures of from 4° to 6°C. The pregnant solution warmed to about 10°C in the centrifuging operation. The results of the individual centrifuging tests and the calculated composite results of the tests are shown in Table VIII.

The primary crystals contained 8.15 pct of the vanadium, 85.18 pct of the phosphorus, and 11.22 pct of the chromium present in the primary solution. To free the primary crystals of vanadium and chromium the crystals were dissolved in water, trisodium phosphate was crystallized from the solution, and the crystals separated from solution by centrifuging. Three series of crystallization and centrifuging tests were required to handle all of the solution. The phosphorus content of the solution to the first series of crystallization tests was 54 g per liter, but in the last two series the phosphorus content was adjusted to 45 g per liter. In each 1600 milliliter batch crystallization run the batch was cooled to -1°C and then stored in the refrigerator until the four batches required for the centrifuging test had accumulated. In the first centrifuging test the crystal-solution mixture was introduced into the centrifuge at 4°C, and secondary solution discharged from the centrifuge at 11°C. The crystals were washed in the centrifuge with 200 milliliters of ice water. In the second centrifuging test the crystal-

solution mixture was introduced into the centrifuge at 1°C and the secondary solution discharged at 9°C. The conditions for the third centrifuging test were the same as for the second.

The crystal product from this step in the process is the final trisodium phosphate product, and in this test it contained 1.08 pct of the vanadium from the primary solution. Chemical analysis of a sample of the dried crystal product showed a phosphorus content of 18.3 pct. The results of the secondary crystallization tests are shown in Table IX.

Assuming that all of the phosphorus extracted from the calcine is recovered in the form of trisodium phosphate except that lost in the final pregnant solution, the calculated phosphorus recovery for this test is 91.7 pct.

Perhaps the most noteworthy feature of this process is the addition of phosphoric acid to the pregnant solution from the primary crystallization step so that the solution can be freed of about 90 pct of its phosphorus by crystallization. For every gram of vanadium in the pregnant solution there was 0.74 g of phosphorus. Phosphoric acid was added to the pregnant solution to adjust the pH to 8.8 so that disodium phosphate would crystallize from solution on cooling. In this test the phosphoric acid addition amounted to approximately ½ g of phosphorus per gram of contained vanadium. After the tertiary crystallization and centrifuging operations, the vanadium-phosphorus ratio in the final pregnant solution was 1:0.078.

The adjusted solution was crystallized and centrifuged in the same manner as previously, with three centrifuging tests, each on the combined product of four 1600 milliliter batch crystallization runs. The crystallization temperature was -3°C. The crystal-solution mixtures were introduced into the centrifuge at 6° to 7°C. In this centrifuging operation the

crystals were not washed. The disodium phosphate crystal product of continuous plant operation would be recycled to the primary solution storage tank, and the solution would go to the hydrolysis operation. The results of the tertiary crystallization and centrifuging operations are shown in Table X.

The phosphorus content of the composite pregnant solution from the tertiary crystallization step was 0.98 g per liter. After further precipitation of phosphorus from this solution with lime and/or calcium chloride in three batch operations, red cake was recovered from each of the batches by hydrolysis. The results of the hydrolysis tests are summarized in Table XI.

The calculated overall recovery of vanadium as black cake for the entire test is 84.4 pct, if the recovery obtained in hydrolysis test 3 is applied to the entire hydrolysis operation and if it is assumed that all of the vanadium leached from the calcine is recoverable as black cake, except that in the trisodium phosphate product, the calcium phosphate product, the barren solution, and the red-cake washings.

Most of the test work on the recovery of chromium from barren solution was done on solution from this test, although the tests are described in a preceding section. The results indicated that as much as 99 pct of the chromium was recovered from the barren solution in a chrome yellow product that contained over 93 pct PbCrO₄. In the initial leaching, 69.3 pct of the chromium in the calcined ferrophosphorus was extracted. There were small chromium losses in the trisodium phosphate, black-cake, and calcium phosphate products. Assuming that 99 pct of the chromium could be precipitated from barren solution, as some of the batch tests indicated, the overall recovery of chromium as chrome yellow would be at least 65 pct.

Conclusions

The largest phosphate reserve in the United States occurs in the Phosphoria formation of Montana, Idaho, Wyoming, and Utah. An unusual feature of this great reserve is its content of small percentages of vanadium, chromium, and other metals. In the production of elemental phosphorus by electric furnace smelting most of the vanadium and other metals collect in the byproduct ferrophosphorus. To the authors' knowledge, the western ferrophosphorus currently produced is not being treated to recover vanadium or other values contained in it. By use of the tristage crystallization process described in this paper, vanadium black-cake, chrome yellow, and a valuable trisodium phosphate product could be recovered from western ferrophosphorus.

The tristage crystallization process starts with roasting of the vanadiferous ferrophosphorus with

soda ash and salt, followed by water leaching to extract vanadium, phosphorus, and chromium. Commercial grade trisodium phosphate is produced from the primary leach solution by two crystallization and centrifuging operations. The pregnant solution from the primary crystallization step contains the recoverable metal values and more phosphorus than can be tolerated in the vanadium hydrolysis step. A third crystallization and centrifuging step, involving addition of phosphoric acid to the pregnant solution, removes about 90 pct of the remaining phosphorus as disodium phosphate and leaves only about 1 g per liter of phosphorus in the final pregnant solution. The disodium phosphate crystals are recycled to the primary solution, increasing the yield of the trisodium phosphate product. After further phosphorus purification by addition of calcium ion, the final pregnant solution is hydrolyzed to precipitate vanadium as red cake. The red cake is fused at 800°C to produce black cake, which is the usual form of vanadium for use in the production of ferrovanadium and vanadium chemicals. Chromium is precipitated as chrome yellow by addition of lead nitrate or acetate to the solution remaining after hydrolysis of the vanadium. Results of a simulated plant test indicate that about 85 pct of the vanadium, 65 pct of the chromium, and 91 pct of the phosphorus contained in western ferrophosphorus can be recovered in valuable products.

Acknowledgments

The research reported in this paper was done by the Ferrous Metals Branch, Region II, Bureau of Mines, at the Northwest Electrodevelopment Laboratory. It was part of the general program of the Bureau of Mines to develop and conserve the Nation's mineral resources. The authors acknowledge the advice of Stephen M. Shelton, Regional Director, under whose general supervision the investigation was made. Credit is due Mark Wright, now Assistant Regional Director, W. F. Holbrook, Head of the Chemical Section, and other members of the analytical staff for the many analyses of test products.

The cooperation of J. G. Miller, Resident Manager, Westvaco Chemical Div., Food Machinery & Chemical Corp., in supplying ferrophosphorus produced at the division's Pocatello, Idaho, phosphorus smelter is gratefully acknowledged.

Directional Properties of 2S Aluminum

by K. T. Aust and F. R. Morral

The preferred orientation and earing characteristics of 2S aluminum were studied. An empirical correlation was obtained relating earing behavior and variation of mechanical properties for face-centered cubic metals. Strain-ratio measurements for 2S were found to be in good agreement with Hill's theory of plastic anisotropy.

DIRECTIONALITY in sheet metals may be revealed by earing in a cupping test, or by the variation of mechanical properties of tensile specimens taken at different angles to the rolling direction. However, no simple correlation appears to exist between earing and variation in mechanical properties in metals and alloys studied.¹⁻⁵

Aluminum of commercial purity (known as 2S, with a specified minimum of 99.0 pct Al) cast by the direct casting process was chosen in the present investigation since ears at 45° or 0°, 90° can readily be obtained. Preferred orientation is often the principal cause of uneven metal flow, such as earing, and variation in mechanical properties. Consequently, the preferred orientation characteristics of 2S aluminum were initially studied using both X-ray diffraction and micrographic techniques. The variation of mechanical properties with angle to the rolling direction was next determined in an effort to clarify the apparent lack of correlation of earing behavior with mechanical properties for face-centered cubic metals. Strain-ratio^{6,7} measurements

* The strain-ratio values are obtained by deriving the slope of the curve $\ln W/W_0$ vs $\ln T/T_0$ where W_0 and T_0 are the initial width and thickness respectively of the tensile specimen and W and T are the width and thickness at an arbitrarily chosen percentage of elongation.

were finally conducted to determine first, if the maximum values of the strain ratio occurred at the earing positions, and second, if Hill's theory of plastic anisotropy⁷ is applicable to other face-centered cubic metals such as aluminum.

Detailed treatments, working, and heat treating are not given in this paper since this study is not concerned with the methods to produce earing, but to correlate earing with other properties and characteristics of the material. The percentage of earing was measured using the formula specified by the

Aluminum Association, $\frac{x-y}{x} \times 100 = \text{pct earing}$,

K. T. AUST, Junior Member AIME, formerly with Kaiser Aluminum & Chemical Corp., is now associated with Johns Hopkins University, Baltimore, and F. R. MORRAL, Member AIME, is Head, X-Ray Dept., Div. of Metallurgical Research, Kaiser Aluminum & Chemical Corp., Spokane, Wash.

where x is the height of the ear and y is the height of the valley from the bottom of the cup.

Preferred Orientation Characteristics of 2S

X-ray Studies: Beck and coworkers⁸ have determined that the rolling texture of 2S after 95 pct cold reduction may be approximately described by four equivalent ideal orientations near (123) $[\bar{1}\bar{2}1]$. Also, the recrystallization or annealing texture of 2S aluminum consists of four components of the (123) $[\bar{1}\bar{2}1]$ type, retained from the rolling texture, and of a (100) $[001]$ or cube texture component.⁹ Fig. 1 illustrates the typical appearance of deep drawn earing cups with the corresponding X-ray diffraction patterns. The X-ray patterns were taken with copper radiation using the structure-integrating method¹⁰ in which the specimen is scanned during the X-ray exposure. The rolling direction was vertical and the rolling plane was perpendicular to the horizontal X-ray beam. It was found that an increase in the retained rolling texture component resulted in a greater 45° ear height, while an increase in the recrystallization texture component (i.e., cube texture) caused greater 0°, 90° earing.

X-ray diffraction studies of 2S cold rolled to final thickness followed by a final anneal have shown that the rolling texture, and also the retained component of the rolling texture after annealing, are increased with greater cold-rolling reduction.

The preferred orientation characteristics of 2S sheets given an intermediate anneal between cold rolling followed by a final anneal were found to depend on the position of the intermediate anneal during cold rolling. For instance, three identical samples of 2S homogenized ingot, each 1 in. thick, were given the following cold-rolling and annealing treatments: 1—50 pct reduction, intermediate anneal, 96 pct reduction to 0.020 in. and a final anneal; 2—75 pct reduction, intermediate anneal, 92 pct reduction to 0.020 in. and a final anneal; and 3—90 pct reduction, intermediate anneal, 80 pct reduction to 0.020 in. and a final anneal. The intermediate and final annealing treatments consisted of a 70°F per hr heating rate, held 6 hr at 800°F and air cooled.

Typical X-ray patterns after each of these treatments are shown in Fig. 2. It was evident that after treatment 1, the retained rolling texture component predominated; after treatment 2, the retained roll-

c—Typical for recrystallization texture of rolled 2S.

Fig. 1—Earing cups from annealed 2S sheets with typical corresponding X-ray patterns.

ing texture component decreased and the cube texture component increased. After the treatment outlined in 3, the rolling texture component again decreased with very little cube texture, approaching a random orientation texture. These results illustrate the changes in the amounts of preferred orientation which may occur when the position of a single intermediate anneal is varied.

The importance of final annealing temperature on the preferred orientation and earing characteristics of many face-centered cubic metals and alloys has been demonstrated by various investigations.¹¹⁻¹⁴ For instance, it was determined that the $0^\circ, 90^\circ$ ears of copper¹⁴ and cupronickel¹² increased in size as the final annealing temperature was raised. The height of 45° ears in brass also increased with the temperature of the final anneal.^{11, 13} The effect of final annealing temperature on the earing behavior of 2S was determined and is shown in Fig. 3. The multi-

ple curves of Fig. 3 were obtained by various cold-rolling and intermediate annealing treatments prior to the final anneal. Therefore, the ear height and ear direction at any one final annealing temperature depended on the previous treatment. Generally, a decrease of 45° ear size and an increase of $0^\circ, 90^\circ$ ear size resulted with higher final annealing temperatures. X-ray studies have revealed an increase of the cube orientation texture in 2S after annealing at higher temperatures. For both copper¹⁴ and brass,^{11, 13} it was believed that the increased grain size with resulting greater ease of plastic flow was the more important influence on increase in ear height with temperature of the final anneal. However, if the larger grain size was a contributing factor to the ear height of 2S, then both 45° and $0^\circ, 90^\circ$ ear sizes would be expected to increase as the final annealing temperature was raised. Since this was not observed, the more perfectly developed

cube orientation texture is believed to be the primary reason for the variation of ear size of 2S with change in final annealing temperature.

Micrographic Studies: The orientations present in aluminum sheet were studied micrographically, by using the new technique with an anodized film and polarized light.^{9, 15, 16}

It was observed that the cube grains appeared black under polarized light and remained black even though the microscope stage was rotated through 360°. However, the other orientations changed colors from white to gray to black, and vice versa, for each 45° rotation of the stage. It was,

Fig. 4—Relationship between percentage of 0°, 90° ear height in drawn cup and percentage of cubically aligned grains in microstructure.

therefore, possible to determine the percentage of cubically aligned grains. Two micrographs were taken from the same locations of a specimen before and after a 45° rotation of the microscope stage. The two negatives were superimposed such that identical grains coincided. A photographic print was then made from the two superimposed negatives. Those grains which were now black on the print possessed the cube orientation texture. The percentage of cubically aligned grains was then determined from the photographic prints using grain count techniques to an accuracy of approximately ± 5 pct. These determinations were carried out near the center of the cross section of annealed 2S sheets having different 0°, 90° ear heights. The percentage of 0°, 90° ear height was plotted as a function of the percentage of cubically aligned grains in Fig. 4. A similar relationship was also found by Baldwin¹⁷ for annealed copper strip. It is noteworthy for annealed

2S that sheets containing less than 40 pct cubically aligned grains still can produce ears at 0° and 90° to the direction of rolling.

Variation of Mechanical Properties of Annealed 2S

Tensile tests were conducted at every 10° from 0° to 90° to the direction of rolling, for annealed 2S sheets having different earing characteristics. The results are shown in Figs. 5 to 8. Differences in grain size produced by the treatments given influenced the actual values of the mechanical properties. However, the variation of tensile strength and percentage of elongation was a function of the angle the axis of the tensile specimen made with the rolling direction.

When 45° ears occurred in the cups, minimum tensile strength and maximum elongation was obtained in approximately the corresponding position in the sheet, i.e., at 45° to the rolling direction (Figs. 5 and 6). These results therefore agreed with those on brass,⁸ also having 45° ears. When the crests of ears were located in the 0° and 90° positions the tensile values were approximately a minimum and the elongation values generally approached a minimum in the corresponding positions (Figs. 7 and 8). The results for the variation in elongation of 2S were somewhat obscured by the effect of mechanical fibering. However, the general correlation of earing and variation in tensile strength was apparent. The minimum elongation in 2S and copper⁸ occurred in approximately the corresponding positions of 0° and 90° earing. The minimum elongation of copper was attributed to the high proportion of (100) [001] texture.¹⁸ It was shown in the present work that 2S annealed sheets having 5 pct and 9 pct 0°, 90° ear heights (as in Fig. 8) contained a large proportion of cube texture. Therefore, it is believed that the cube texture component of the annealing texture

Figs. 5 (upper) and 6 (lower)—Directionality of tensile properties of annealed 2S sheets with different 45° ear heights.

Figs. 7 (upper) and 8 (lower)—Directionality of tensile properties of annealed 2S sheets with different 0°, 90° ear heights.

was also responsible for the minimum elongation values in annealed 2S having 0°, 90° ear directions.

One obvious anomaly still remained; namely, with 0°, 90° earing, 2S aluminum showed a minimum tensile strength and copper a maximum tensile strength, in the 0° and 90° directions of rolling. Richards¹⁸ has indicated that the 0°, 90° positions of ears in copper corresponded to the direction of minimum true tensile strength. Richards pointed out that an approximate estimation of the true tensile stress at fracture can be made by multiplying the

tensile strength value by a factor, $1 + e$, where e is the elongation of the test piece expressed as a fraction of the gage length. By applying the $1 + e$ approximation, the true tensile strength of 2S was also determined to be a minimum at 0° and 90° to the rolling direction. Therefore, the 0°, 90° earing behavior of both copper and 2S can be correlated with the minimum true tensile strength values in corresponding 0° and 90° positions. The same relationship held for annealed brass and 2S having 45° earing positions, since the directions of maximum and minimum true stress values are identical with the positions of the maximum and minimum tensile strength values.

Therefore, a general empirical correlation exists between earing and variation of mechanical properties for face-centered cubic metals. The general tendency with 0°, 90° or 45° earing directions is the occurrence of minimum true tensile strength in approximately the same direction of ear formation. With 45° earing, the elongation is usually a maximum at about 45° to the rolling direction. However, with 0°, 90° earing, the elongation generally approached a minimum in the 0° and 90° positions.

Strain Ratios of Annealed 2S

The previous correlation of directionality and earing tendencies is still only qualitative. The theory of plastic anisotropy advanced by Hill⁷ appears to be a promising quantitative approach to the problem. According to this theory, the important factor controlling the positions of the ears is the relation between the ratios of the components of the stress and the plastic strain increment. The relevant test is the measurement of strain ratios in tension tests. The theoretical treatment, described by Bourne and Hill,⁶ resulted in the following equation:

$$\frac{\ln W/W_0}{\ln T/T_0} = \frac{H + (2N - F - G - 4H) \sin^2 \alpha \cos^2 \alpha}{F \sin^2 \alpha + G \cos^2 \alpha} = r(\alpha) \quad [1]$$

W_0 and T_0 are the initial width and thickness respectively of the tensile specimen and W and T are the width and thickness at an arbitrarily chosen

Figs. 9 (left) and 10 (right)—Contraction of unit width and unit thickness during tensile tests of two samples of annealed 2S having 45° ears and 0°, 90° ears.

percentage of elongation (usually every 5 pct). F , G , H , and N are parameters specifying the constant state of anisotropy. The term r is the strain ratio at an angle α to the rolling direction.

The validity of the theory expressed in Eq. 1 can be checked by comparing it with the experimental results of strain ratios at various angles to the rolling direction. According to Bourne and Hill, if N is less than both $F + 2H$ and $G + 2H$, the ears are in the 0° and 90° positions. However, if N is greater than both $F + 2H$ and $G + 2H$, the ears are in the 90° positions where γ may be obtained from

$$\tan^2 \gamma = \frac{N - G - 2H}{N - F - 2H} \quad [2]$$

The above theoretical considerations were found to be in good agreement with the experimental data for copper and brass having four ears.⁶ The following experiments were conducted to determine if Hill's theory of plastic anisotropy may be generalized to include other metals, such as aluminum.

Two sheets of annealed 2S aluminum (0.020 in. thick) were used throughout these tests, one sheet having four ears of 13 pct height at 45° and the other having four ears of 13 pct height at $0^\circ, 90^\circ$ to the rolling direction, after deep-drawing. Standard tensile specimens in duplicate were milled from these sheets at various angles to the rolling direction, $0^\circ, 22.5^\circ, 45^\circ, 67.5^\circ$, and 90° . The gage length was 2 in. and the width 0.5 in. Width and thickness measurements of the tensile specimens were taken with a micrometer reading to 0.0001 in., at every 5 pct elongation from 0 pct to the stage at which necking began. The values of the width and thickness were expressed in terms of unit width (W/W_0) and unit thickness (T/T_0).

The unit width and unit thickness values for the two sheets of annealed 2S having 45° and $0^\circ, 90^\circ$ ears were plotted logarithmically in Figs. 9 and 10. It is evident that the rate of contraction of thickness with respect to that of the width is a function of the angle between the axis of the tensile specimen and the rolling direction.

Values of strain ratios (r) were plotted as a function of the angle α between the rolling direction and the axis of the tensile specimen in Fig. 11. The maximum values of r were found to occur in the same positions as the ears; i.e., for 45° ears, r is a maximum at 45° and for $0^\circ, 90^\circ$ ears, r is a maximum at 0° and 90° . It is concluded that the occurrence of maximum values of the strain ratio at the actual earing positions is not only true for copper and 70:30 brass but is also the case for 2S aluminum and perhaps for all face-centered cubic metals. Baldwin et al.⁵ have explained the relationship between unit width and unit thickness, for copper samples cut at 45° to the rolling direction, by the manner in which the crystallites deform.

The theoretical relation of Hill (Eq. 1) was checked with the experimental results of r for annealed 2S over the whole range of angles to the rolling direction. The parameters giving four ears at 45° corresponding to the curve in Fig. 11 are: $F:G:H:N = 1:0.8:0.35:3.2$. According to the theory of Hill, if N is greater than both $F + 2H$ and $G + 2H$, as is true in the present case, the ears are in the 90° positions. The angle γ was determined to be 47° from Eq. 2, i.e., the ears should form at 43° . This agrees well with the experimental value of 45° ears.

Fig. 11—Variation of strain-ratio " r " with angle to the rolling direction for annealed 2S sheets having 45° and $0^\circ, 90^\circ$ ears.

The results shown in Fig. 11 for the annealed 2S sheet having $0^\circ, 90^\circ$ ears were found to give the following parameters: $F:G:H:N = 1:1:1:1.6$. The theory predicts ears in the 0° and 90° positions when N is less than both $F + 2H$ and $G + 2H$, which is again in agreement with experiment.

Thus, the theory of plastic anisotropy advanced by Hill was found to be in good agreement with the experimental data for annealed 2S sheets. Since similar conclusions were reached for copper and 70:30 brass,⁶ it is concluded that Hill's theory may be applicable to all face-centered cubic metals. Consequently, Hill's method of predicting earing positions from measurements of strain ratios in tension tests is regarded to be of more fundamental significance than the usual empirical attempts to correlate rupture properties with the earing tendency of a metal.

Summary

The occurrence of $0^\circ, 90^\circ$ earing in annealed 2S sheet was related to the cube texture component, while 45° earing was associated with the retained rolling texture component. The preferred orientation characteristics of the final annealed 2S sheet were found to depend on the amount of reduction before the anneal, and on the position of an intermediate anneal during the cold-rolling cycle.

Micrographic methods revealed a definite relationship between the $0^\circ, 90^\circ$ earing tendency of 2S aluminum and the percentage of cubically aligned grains. The amount of cube orientation texture increased with higher final annealing temperatures.

The tensile strength and true stress at fracture were a minimum and the elongation a maximum at 45° to the rolling direction when 45° ears occurred in 2S. However, the tensile strength and true stress were minima and the elongation generally approached a minimum at 0° and 90° when ears formed in the 0° and 90° positions. The variation of mechanical properties with earing behavior of annealed 2S was correlated with similar variations for other face-centered cubic metals.

The strain-ratio values were a maximum at 45° or 0° and 90° for annealed 2S sheets that eared at 45° or 0° and 90° , respectively. The theory of plastic anisotropy advanced by Hill was found to be in good agreement with the experimental results for annealed 2S sheets.

Technical Note

Preferential Etch for Use in Optical Determination Of Germanium Crystal Orientation

by R. H. Wynne and Colman Goldberg

WHEN using an optical goniometer to determine crystal orientation¹ it is advantageous to use a preferential etchant so that the etch pits have plane faces which are parallel to crystallographic planes, all of which are of the same "form."

"Westinghouse Silver Etch" (WAg), a preferential etch for germanium, is made up as follows: 40 ml of 49.7 pct hydrofluoric acid, 20 ml of 70.7 pct nitric acid, and 40 ml of distilled water containing 2.0 g of silver nitrate. Examination of metallographs of WAg etched surfaces (Fig. 1, for example) indicates that, regardless of crystal orientation, the faces of the etch pits are (111) surfaces. Optical goniometer examination of these WAg etched surfaces also indicates that the faces of the etch pits are (111) surfaces, i.e., all bright reflections are from (111) planes.

When using an optical goniometer of the type described by Barrett,¹ not only (111) reflections from a WAg etched germanium surface but also other reflections of lower intensity will be observed. These latter reflections can cause confusion. We have used an optical goniometer made from a war surplus astrocompass and a galvanometer lamp. The reflections are observed by using the goniometer in a darkened room and letting the reflected light be in-

Fig. 1—WAg etched germanium surface. Approximately (111) orientation.

cident upon a piece of white paper. The resulting decrease of goniometer sensitivity enables (111) reflections only to be observed. This in turn permits the crystal orientation to be determined in a matter of minutes, since only two measurements are necessary.

The authors wish to acknowledge the help received from R. E. Davis who assisted in making the metallographs and aided the authors in the interpretation of the metallographs.

Some Applications of the Thermodynamic Theory of Irreversible Processes to Physical Metallurgy

by E. S. Machlin

An extension of the thermodynamic theory has been made for the case of irreversible growth processes occurring by the motion of an interface. The theory is applicable to such diverse phenomena as diffusion, growth in recrystallization, continuous grain growth, growth of carbides, etc., growth of eutectoid products, growth in solidification, recovery, "slipless" flow, etc.

THE publication of a recent book¹ has served to focus attention on a very powerful means of treating certain irreversible processes. This method which has been formally described as the thermodynamic theory of irreversible processes is applicable to processes which involve an approach to equilibrium and for which the deviations from equilibrium are small. The irreversible processes can be classified into three groups: chemical reactions, transport processes (diffusion, heat and electrical flows), and relaxation phenomena involving a degradation of internal energy to more stable states. The limits of applicability of the theory can be precisely defined^{1, 2} for each type of irreversible process. For example, in a chemical reaction at constant temperature and pressure, the Gibbs free energy released per mol in the process should be less than the thermal energy, RT .

Another type of irreversible process, which sometimes involves a combination of the first two of the above-mentioned groups, is treated in this paper. This process is one characterized by the motion of an interface separating two regions having different values of free energy and may be briefly described as a growth process. Prigogine² and Herring³ have treated special cases of this type of process.

Previous conscious applications of the theory in metallurgy have been limited to the field of diffusion, one of the transport processes. Darken,⁴ Bardeen,⁵ Prigogine² and others have made significant contributions in this respect. Some other applications of the theory are described in this paper.

The Theory

The thermodynamic theory of irreversible processes is based on the work of Onsager,⁶ DeDonder,⁷ Prigogine² and others. A resume of the theory has been given by Prigogine² and DeGroot.¹ A brief description of the theory follows, although for a complete understanding the reader is urged to read the references.

E. S. MACHLIN, Member AIME, is Assistant Professor of Metallurgy, School of Mines, Columbia University, New York.

Discussion on this paper, TP 3431E, may be sent, 2 copies, to AIME by Dec. 1, 1953. Manuscript, Jan. 18, 1952; revised, Sept. 18, 1952. Cleveland Meeting, October 1953.

It is first assumed that the change in entropy, even for a system removed from equilibrium, is given by

$$dS = [dU + pdV - \sum_i \mu_i dn_i - \sum_k P_k dx_k] T^{-1}$$

Using this expression, the irreversible entropy production in the system is calculated by subtracting the contribution to the change in entropy of the system by transfer of heat, work, or matter from the surroundings. Thus, for example, the irreversible entropy production of a system at constant temperature and pressure is given by

$$d_i S = -\frac{1}{T} dG \quad (\text{DeDonder}^7)$$

Now it has been shown by Prigogine,² DeDonder,⁷ and DeGroot¹ that the rate of irreversible entropy production $d_i S/dt$, when calculated in the manner suggested, can be written as a sum of products of conjugate forces X_k and fluxes J_k , i.e.,

$$\frac{d_i S}{dt} = \sum_k J_k X_k \quad [\text{I-1}]$$

The assumption is next made that a linear relation exists between a given flux and the forces, obtained from Eq. I-1, i.e.,

$$J_i = \sum_k L_{ik} X_k \quad (i = 1, 2, \dots, n) \quad [\text{I-2}]$$

Generally, there is a degree of freedom in choice of the fluxes and forces. However, for all the choices consistent with Eq. I-1 the Onsager⁶ relations, based on the principle of microscopic reversibility, namely, $L_{ik} = L_{ki}$, are valid. The coefficients L_{ik} , depending upon the choice of the conjugate fluxes and forces, may be more or less dependent upon the parameters defining the state of the system. In general, the proper choice of fluxes and forces utilizing Eq. I-1, makes the coefficients L_{ik} independent of time. Also, because many of the three classes of irreversible phenomena have already been treated,^{1, 2} a proper choice can be made by analogy. In any case, the validity of Eq. I-2, from whatever choice made using Eq. I-1, must be tested by experimentation.

The theory, thus, comprises the following steps: 1—The irreversible entropy production is calculated to yield Eq. I-1. 2—The terms in Eq. I-1 are grouped

to yield what seems to be a logical compilation of conjugate fluxes and forces. 3—The linear relations, Eq. I-2, are set up using these definitions of fluxes and forces. 4—These linear relations are then tested experimentally. 5—The reciprocal relations $L_{ki} = L_{ik}$ are also checked experimentally.

Upon experimental verification of the predicted results for a large number of diverse types of irreversible processes, it has been found that the theory provides a neat, concise description of irreversible phenomena in the state not too far removed from equilibrium.* Thus, the theory fulfills one of the

* The limit of applicability of the theory can be made precise for each type of irreversible process.

goals of scientific endeavor. It is beyond the scope of this paper to illustrate the breadth of applicability of the theory. However, an attempt will be made in this paper to illustrate how the theory rationalizes growth phenomena on the basis of the simple principles just described.

Before concluding this section it is worthwhile to note that the thermodynamic theory in each case comprises the first approximation of the corresponding kinetic description. The thermodynamic theory of irreversible processes is valid, therefore, only when the second term in the expansion of the kinetic description is an order of magnitude smaller than the first term. This situation, for the example of an irreversible process at constant temperature and pressure, exists only when the free energy per atom released in the irreversible process is less than the thermal energy kT . A major advantage of the thermodynamic theory as compared to the statistical mechanical treatment is that the former is independent of any assumption about model. Within its realm of applicability, the theory gives an accurate phenomenological description of nature, quite analogous to the description ordinary thermodynamics gives of the state of equilibrium. An appreciation of this fact can only be gained by reading DeGroot¹ and Prigogine.²

Extension of the Theory

Previous considerations of growth phenomena in the light of the theory have been few. All of these treatments^{2,3} have considered some specific growth process as the resultant of the one or two basic types of irreversible phenomena (transport and chemical reactions) rather than as an entity itself. It occurred to this author that a consideration of the growth process as a separate type of irreversible phenomenon would be extremely simple as compared to previous treatments and would involve no assumption about mechanism.

Growth phenomena at constant temperature and pressure are characterized by the motion of an interface separating two regions having different values of free energy. The basic equation for the rate of production of irreversible entropy per unit area of interface is given by

$$\frac{d_i s_A}{dt} = - \frac{1}{TA} \frac{dG}{dt} \quad [I-3]$$

where G is Gibbs free energy for system; A , the interfacial area; and T , the absolute temperature. In order to use Eq. I-3 in the sense desired (assuming that Eq. I-2 can be applied to the result), the rate of decrease of the free energy must be expressed in terms of the interface. For example, consider the case of a sphere of phase i growing out into the less

stable phase o , and assume that the interfacial energy σ is isotropic. In this case,

$$\frac{dG}{dt} = \frac{\partial G}{\partial R} \frac{dR}{dt} = \{(-g_o + g_i) 4\pi R^2 + 8\pi R\sigma\} \frac{dR}{dt} \quad [I-4]$$

where R is the radius of sphere, and g_o, i the free energy per unit volume of phases o, i , respectively. It should be noted that Eq. I-4 corresponds to the situation where no other parameter that is descriptive of the interface varies with time. For example, in one conceivable growth process—the growth of spheres of cementite from supersaturated ferrite—two additional parameters might vary with time, namely, the thickness of the diffusion layer normal to the interface and the free energy g'_o of that part of the diffusion layer adjoining the interface. In this case two additional terms need to be added to the expansion of dG/dt . Unless otherwise specified the growth phenomena treated in this paper correspond to the situation described by Eq. I-4.

Substituting for dG/dt and A in Eq. I-3, using Eq. I-4, the following equation is obtained:

$$\frac{d_i s_A}{dt} = \frac{1}{T} (\Delta g - 2\sigma/R) \frac{dR}{dt} \quad [I-5]$$

where $\Delta g = g_o - g_i$.

As expected, Eq. I-5 has the form of a product of a force, $\frac{\Delta g - 2\sigma/R}{T}$, and a conjugate flux, dR/dt .

The force is the free energy released per unit advance of a unit area of interface. The flux is the rate of advance of the interface normal to itself. The next step in the theory is to assume that the flux is linearly related to the force, or

$$\frac{dR}{dt} = L_R \frac{\Delta g - 2\sigma/R}{T} \quad [I-6]$$

In words, this assumption of the phenomenological theory is that the rate of advance of an interface is proportional to the free energy released per unit advance per unit area of interface. Eq. I-6 should be applicable to all situations meeting the conditions assumed in the derivation and also the limitation that $(\Delta g - 2\sigma/R) \times \text{atomic volume} \ll kT$.

If now it can be shown that the Eqs. I-3 to I-6, or equivalent equations derived from Eq. I-3, are consistent with experiment, then one use of the thermodynamic theory of irreversible processes will have been demonstrated. Although it is true that Eq. I-6 could have been assumed *a priori*, so could any of a number of other relations have been assumed. The function of the thermodynamic theory in this respect is to provide a criterion which relations of the type Eq. I-6 must satisfy in order to be consistent with the theory. The value of this, or any other, phenomenological theory is the existence of a formalization that describes what appear to be diverse phenomena in terms of some language common to all the phenomena.

Theory Applied to Grain Boundary Migration

Growth of a Recrystallized Grain in a Strained Matrix: Consider the case of a single, spherical, strain-free, monocrystalline grain growing in a polycrystalline strained matrix. Let g_o be the free energy per unit volume of the strained matrix, and

g , the free energy per unit volume of the unstrained matrix. Eq. I-6 applies directly to this case, hence the rate of nucleus growth is given by Eq. I-6, i.e.,

$$\frac{dR}{dt} = \frac{L_r}{T} (\Delta g - 2\sigma/R) = G - B/R \quad [\text{II-1}]$$

This equation states in effect, that after a time t_0 (nearly equal to the induction period), B/R becomes very much smaller than G , and hence that after this time, t_0 , the growth rate is apparently constant. Reasonable estimates of Δg and σ lead to the minimum R for this range as about 10^{-3} cm. This result checks the experimental observations of Mehl and coworkers^{8,9} upon the growth of strain-free crystals in a strained matrix; that is, from observations of strain-free crystals larger than 10^{-2} cm, the growth rate is a constant.

An approximate relation between the induction period and the growth rate can be derived by integrating Eq. I-6 and making suitable approximations. The result is that the induction period is approximately inversely proportional to G , i.e.,

$$t_0 \approx \frac{10 \sigma}{\Delta g G}$$

Thus, a plot of $\log t_0$ vs $\log G$ should yield a straight line having the slope, -1 and the intercept $10 \sigma / \Delta g$ at unit growth rate. Data taken from Anderson and Mehl⁹ have been plotted in this manner in Fig. 1. As shown by the figure, the data for various temperatures and percentage of prior elongation do approximately obey the predicted relations.**

** This result implies that the induction period does not correspond to a time for nucleation, contrary to the assumptions of Anderson and Mehl⁹ and Turnbull.¹⁰

Further, a comparison of the experimental and theoretical intercepts yields a value of 400 for the ratio $\Delta g / \sigma$. Assuming a value of $\sigma = 500$ ergs per sq cm, a value of $\Delta g = 2 \times 10^6$ ergs per cu cm is obtained. This value compares favorably with the value estimated, on the basis of the stored strain energy using 5 pct as the ratio of the energy stored to the work of deformation, namely,

$$\Delta g \text{ (estimated)} = 0.05 \times (\text{work done}) = 0.05 \times 3.5 \times 10^7 = 2 \times 10^6 \text{ ergs per cu cm}$$

If this estimate is meaningful, then about 90 pct of the energy stored during cold work is relaxed by recovery prior to recrystallization. Both these energies when related to one atom are much less than kT . Thus, the application of Eq. I-6 to nucleus growth in recrystallization is justified.

Another interesting result is obtained by considering the contribution of the grain boundaries in the strained phase to Δg . For the data of Anderson and Mehl, this energy corresponds to about $500 \sigma_{s-o}$ (corresponding to a grain size of 530 grains per sq mm). Inasmuch as σ_{s-o} is expected to be of the order of magnitude of σ , but less than σ , this result, when compared to the previously calculated value of $\Delta g = 400 \sigma$, implies that the surface energy contribution to Δg is as important as the strain energy contribution. The fact that both the initial grain size and the amount of deformation affect the growth rate is confirmation of this conclusion.

It is instructive to separate the strain energy term, Δg_s , from the surface energy term, Δg_b , in Δg proper. Whenever, the growing strain-free and

internal, boundary-free, material is surrounded by a matrix comprising both strain and grain boundaries, then Eq. I-6 becomes

$$\frac{dR}{dt} = \frac{L_r}{T} (\Delta g_s + \Delta g_b - 2\sigma/R) \quad [\text{II-3}]$$

where

$$\Delta g = \Delta g_s + \Delta g_b$$

When R is much larger than the average diameter of the grains surrounding the growing grain, then

$$\Delta g_b = A \cdot \sigma_{s-o}$$

where A is the grain boundary area per unit volume, sq cm/cu cm, and σ_{s-o} is the interface energy between strained grains per unit area.

Secondary Recrystallization: The growth of exaggerated grains in secondary recrystallization can be understood on the basis of Eq. II-3. For the case of secondary recrystallization, $\Delta g_s = 0$. Hence, the equation becomes simply

$$\frac{dR}{dt} = \frac{L_r}{T} \left(\Delta g_b - \frac{2\sigma}{R} \right)$$

This dependence of growth rate upon the radius has been obtained experimentally by Rosi et al.¹¹ in the secondary recrystallization of silver. In their case, measurements of growth rates have been made during the induction period which confirm Eq. II-4 qualitatively. More information is required before a quantitative check can be made. They found that R^* defined by

$$R^* = \frac{2\sigma}{\Delta g_b}$$

was about twice the average matrix grain radius. R is the smallest grain radius of the secondary type which can grow spontaneously outward. Thus, as expected, the necessary and sufficient condition for secondary recrystallization is that the secondary grain radius R obey the criterion

$$R > R^* = \frac{2\sigma}{\Delta g_b} = CD_{\text{avg.}} \quad [\text{II-5}]$$

where $D_{\text{avg.}}$ is the average matrix grain size (diameter) and C is a constant (equals 1 for two dimensional recrystallization); while the secondary grain is surrounded by primary grains. If the average grain diameter is restricted in its growth, then secondary growth can occur at a fast rate. If on the other hand the matrix grains can grow, the rate of growth of secondary grains will either be small or nonexistent.

No limit is placed by the theory on the origin of the secondary grains. They can be formed by growth of existing grains which obey the growth criterion Eq. II-5, or a similar criterion derived from Eq. II-3 whenever Δg_s is not zero across some grain boundaries (some internal strains exist), or by a true recrystallization. It is believed however, that the first two alternatives are the most reasonable.

Continuous Grain Boundary Migration: The last case that can be treated under the general classification is that defined by $\Delta g_s = \Delta g_b = 0$. This is the case of grain boundary migration under a surface energy gradient. For this special case

$$\frac{dR}{dt} = \frac{L_r}{T} (-2\sigma/R) \quad [\text{II-6}]$$

Thus, grain boundary migration of this type is characterized by a decreasing dR/dt , rather than an increasing dR/dt . In other words, migration is always in the direction of the center of curvature. An extension of this concept to the continuous grain growth that occurs after recrystallization implies, as expected, that grain growth occurs by the disappearance of grain boundaries.

An interesting effect is predicted if impurities travel with the grain boundary, such that, as the total boundary area decreases, the concentration of impurities at the grain boundary increases. In this event, the differentiation of the free energy in Eq. I-4 introduces another term into the bracketed term of Eq. II-6, namely,

$$-\sum_i \frac{\partial \sigma}{\partial C_i} \frac{\partial C_i}{\partial R}$$

But

$$C_i = N_i/4\pi R^2$$

where N_i is the total number of impurity atoms of type i traveling with the grain boundary. Thus,

$$\frac{\partial C_i}{\partial R} = -N_i/2\pi R^3$$

Let

$$K_i = \frac{\partial \sigma}{\partial C_i} \frac{N_i}{2\pi}$$

then Eq. II-6 becomes

$$\frac{dR}{dt} = \frac{L_r}{T} (\sum K_i/R^3 - 2\sigma/R) \quad [\text{II-7}]$$

For positive values of $\partial \sigma / \partial C_i$, because the net effect of grain boundary migration in ordinary grain growth is to produce grain boundaries having larger R , there will be a limitation to the size of the grains produced, given by

$$\sum_i K_i/R^3 = 2\sigma/R$$

For negative values of $\partial \sigma / \partial C_i$, when $\sum_i K_i/R^3$ is large compared with $2\sigma/R$, the approximate law of grain growth predicted by Eq. II-7 is***

*** This method follows the assumption made by others that $D \sim R$, or that $dD/dt = -2 dR/dt$.

$$D = \left(\frac{4L\sum K_i}{T} \right)^{1/4} t^{1/4}$$

When $\sum K_i/R^3 \ll 2\sigma/R$, the corresponding result is

$$D = \left(\frac{L4\sigma}{T} \right)^{1/2} t^{1/2}$$

Experimentally, it is found that the exponent of the time, t , varies between $1/4$ and $1/2$ as just predicted. Thus, the explanation for the time dependence of grain growth may involve an effect of grain boundary composition upon the surface energy. It is significant in this respect that the exponent is found to approach $1/2$ with increasing temperature of grain growth and with increasing purity of the matrix. This former trend is what would be expected, because as the temperature is increased the concentration of impurities at the boundary is decreased. The exponent $1/2$ corresponds to no impurities in the grain boundary.

Finally, the result obtained by Zener, namely that the limiting grain diameter depends upon the particle impurities according to

$$D = \frac{2r}{f}$$

where r , the average radius of particles, and f , the volume fraction of particles, is also obtained from Eq. I-4, when the grain boundary area intersected by the particles is taken into account.

Effect of Diffusion across Boundary on Grain Boundary Migration Rate: In view of the fact that both grain boundary migration⁸ and diffusion² occur as a result of vectorial forces, interaction effects are to be expected whenever these phenomena occur simultaneously. The phenomenological equations should then take the form

$$\frac{dR}{dt} = \frac{-L_{11}}{T} \frac{2\sigma}{R} - \sum_i L_{1i} \frac{\partial \mu_i}{\partial R}$$

$$\frac{dm_i}{dt} = \frac{-L_{i1}}{T} \frac{2\sigma}{R} - \sum_k L_{ik} \frac{\partial \mu_k}{\partial R}$$

$$L_{11} = L_{11}$$

where dm_i/dt is the number of atoms of kind i flowing across unit area of the boundary per second. These equations apply to the cases of cylindrical or spherical symmetry in μ_i and the grain boundary and isotropy in σ . Equivalent equations can be derived for nonsymmetrical configurations.

The qualitative implications of these equations are rather obvious. The grain boundary migration behavior should be materially affected by diffusion across the boundary, especially for the case of unequal diffusion rates (a net current of vacancies). No quantitative data are as yet available to check the equations. One of the predictions that can be made on the basis of Eq. II-8 is that for sufficient net diffusion into a spherical grain, the grain may be made to grow rather than disappear.

Effect of Temperature Gradient, etc. on Grain Boundary Migration: Another interesting interaction should occur between grain boundary migration and either a flow of electrical charge or heat across the boundary. These effects should be second order compared to the effect of diffusion across the boundary. The stationary states of zero flow of charge or heat imply that a nonzero electric potential and temperature differential, respectively, will exist across the moving interface and will be proportional to the curvature and to the interface energy σ . In particular, for the flow of heat, the phenomenological equations are

$$\frac{dR}{dt} = \frac{-L_{11}}{T} \frac{2\sigma}{R} - \frac{L_{1u}}{T^2} \text{grad } T$$

$$\frac{dQ}{dt} = \frac{-L_{u1}}{T} \frac{2\sigma}{R} - \frac{L_{uu}}{T^2} \text{grad } T \quad [\text{II-9}]$$

The stationary state $dQ/dt = 0$, yields the equation

$$\Delta T = - \frac{L_{u1}}{L_{uu}} T \frac{2\sigma}{R}$$

Here ΔT represents the temperature increase due to the transfer of energy across the grain boundary analogous to the Dufour effect¹ in diffusion. The magnitude of ΔT is expected to be less than 10^{-3} °C.

Theory Applied to Rate of Growth of Stable Phase

Consider a spherical region of the stable phase growing in a supercooled or superheated matrix. If the theory is applicable to this phenomenon, then the

rate law should be given by Eq. I-6, where g_o is the free energy per unit volume of the supercooled or superheated matrix and g_i is the free energy per unit volume of the stable phase. Here again σ is the interfacial energy per unit area.

For the case of uniform growth of a crystal comprising a single component from the vapor phase, the bracketed term of Eq. I-6, $\Delta g - 2\sigma/R$, is proportional to the difference between the actual and equilibrium values of the vapor pressures. The experimental observations are in agreement with this rate equation for the case of uniform growth.¹² In experiments, such as those just described, whenever the change in free energy per unit volume in the presence of plane interfaces can be determined with a given accuracy, then it should be possible to determine σ with the same percentage accuracy. It is necessary, however, in order that the term $2\sigma/R$ be significant that Δg be small, i.e.,

$$\Delta g = \Delta h \Delta T/T_o$$

where Δh is the enthalpy of phase change per unit volume and T_o is the temperature of equilibrium for phase change. In this case errors in σ are likely to be large.

Whenever two irreversible processes such as diffusion and chemical reactions are involved in the motion of an interface, Eq. I-6 must be re-examined to see whether it applies to the physical situation being considered. For certain special cases, where the diffusive flux is linearly related to the rate of motion of the interface (as a result of the conservation of mass), Eq. I-6 can still be applied. However, there are many examples of growth processes where this simple picture is inadequate and a more detailed treatment is required. In all these cases it should be remembered that a chemical reaction involves a scalar flux while diffusion involves a vector flux. There can be no interactions between them in the sense of the theory; that is, in the event of a homogeneous distribution in the unstable phase having the correct stoichiometric relationship between components, the heterogeneous chemical reaction, proceeding by an interface motion, will not induce diffusion. An example of such a situation is the growth of an ordered phase within a disordered lattice, which incidentally should conform to Eq. I-6. These complex processes are outside the scope of the present treatment, but within the scope of the thermodynamic theory.

Theory Applied to Growth of Stable Phase in Supersaturated Matrix

As indicated in the last section, whenever a growth process involves both a chemical reaction as well as diffusion, it is worthwhile deriving the rate equations from first principles, Eq. I-3. In general, the growth of a stable phase from a supersaturated matrix involves both these irreversible processes.

Growth of Noncoherent Precipitates: Consider the growth of a spherical precipitate. There are two fluxes to consider. Namely, a diffusive flux and a chemical reaction. The rate of growth is directly proportional to the rate at which the chemical reaction $o' \rightarrow i$ proceeds, and is given by

$$\frac{dR}{dt} = \frac{L_o}{T} (\Delta g - 2\sigma/R)$$

where $\Delta g = g_o' - g_i$, the difference in free energy per unit volume (for a plane interface) between the

regions just before and just after the interface. The free energy g_o' may vary with time.

The assumption will be made that there are at most only two constituents which can diffuse (in addition to vacancies). For each constituent the diffusive flux will be given by

$$J_i = -L_{ii} \frac{\partial \mu_i}{\partial x} - L_{ik} \frac{\partial \mu_k}{\partial x}$$

where $\partial \mu_i / \partial x$ is the gradient of chemical potential of species i normal to the interface. As pointed out by Bardeen and Herring⁵ the term $L_{ik} \frac{\partial \mu_k}{\partial x}$ involves a factor which is generally an order of magnitude smaller than the diagonal factor. Hence, it will be neglected in the following. Now, for the case of diffusion adjacent to the interface, because diffusion is normal to the interface, by the conservation of mass

$$-J_i = \frac{d}{dt} \frac{(C_o)_i - (C_o')_i}{2} h = \frac{(C_o)_i - (C_o')_i}{2} \frac{dh}{dt} - \frac{h}{2} \frac{d(C_o')_i}{dt}$$

where $(C_o)_i$ is the concentration of i in phase o ; $(C_o')_i$ is the concentration of i in phase o' at interface, and h is the distance normal to interface where gradient of concentration of i exists. In this equation the second factor will be assumed small compared to the first factor. Thus, to a first approximation, the relation

$$\frac{(C_o)_i - (C_o')_i}{2} \frac{dh}{dt} = L_{ii} \frac{\Delta \mu_i}{h}$$

is obtained by equating the two expressions for J_i . Now,

$$\Delta \mu_i = (\mu_o)_i - (\mu_o')_i$$

Although both $(\mu_o')_i$ and $(C_o')_i$ should vary slightly with time, it will be assumed that the variation is sufficiently small as to leave the ratio $\Delta \mu_i / \Delta C_i$ invariant with time compared to the variation of h with time. Hence, separating variables and solving for h ,

$$\frac{h^2}{t} = 4L_{ii} \frac{\Delta \mu_i}{\Delta C_i}$$

This is the relation obtained from diffusion theory, i.e., the variable $x^2/t = \text{constant}$.

One more relation exists as a result of the conservation of mass, namely,

$$-J_i = \{(C_i)_i - (C_o')_i\} \frac{dR}{dt}$$

where $(C_i)_i$ is the concentration of i in phase i . Equating this expression for J_i to $L_{ii} \Delta \mu_i / h$, and substituting for h , then

$$\frac{dR}{dt} = K/t^{1/2} \tag{II-10}$$

where

$$K = (L_{ii} \Delta \mu_i \Delta C_i)^{1/2} \{(C_i)_i - (C_o')_i\}$$

In this equation K is slightly dependent on time.

Eq. II-10 has been obtained independently by Zener¹⁸ and is consistent with the data on growth of spherical carbides in supersaturated ferrite. It is interesting to note that if $(C_o')_i$ is assumed to be the composition of i in equilibrium with the stable

phase, then $\Delta g - 2\sigma/R$ equals zero, and the interface would not move. Hence, $(C'_e)_i$ cannot be the equilibrium composition, contrary to some previous treatments of this problem.

Growth of Pearlite: In order to obtain an expression for the growth rate of pearlite it is necessary to consider three irreversible processes: diffusion, the chemical reaction austenite \dagger to ferrite and the chemical reaction austenite \dagger to cementite. From

\dagger The austenites in these cases differ from the nominal eutectoid composition.

such a consideration it can be shown that the linear growth rate of pearlite per unit area of interface is given by $\dagger\dagger$

$\dagger\dagger$ The driving force $\Delta g - 2\sigma'/S_p$ times the atomic volume is less than the thermal energy kT .

$$V = \frac{L_p}{T(a + S_p)} \left(\Delta g - \frac{2\sigma'}{S_p} \right) \quad [\text{II-11}]$$

where Δg is the free energy released on converting 1 cu cm of austenite to ferrite plus cementite neglecting interfacial energies; σ' , the interface energy per unit area between ferrite and cementite; S_p , the interlamellar spacing of pearlite; and a , a factor comprising the three mobilities for the three irreversible processes.

An interesting result of the theory is the denial of the validity of Zener's derivation for the maximum growth rate. According to Zener¹⁴ the maximum rate of growth occurs when half the available free energy is used to produce ferrite-cementite interfaces, the remainder being dissipated in the irreversible process of diffusion. It is apparent that if no free energy is dissipated in the chemical reaction, austenite (at interface) to pearlite, then the rate of the chemical reaction would be zero. Hence, not all of the free energy is irreversibly dissipated by diffusional processes. Further, the value of the interlamellar spacing corresponding to the maximum rate of growth is given by

$$(S_p)_{\text{max}} = \frac{4\sigma'}{\Delta g} + a/2 \quad [\text{II-12}]$$

to a good approximation. Zener's result corresponds to $a = 0$. Because the parameter a comprises a positive combination of nonzero constants it cannot equal zero. It is on the order of magnitude of S_p . In fact, if the assumption is made that as much free energy is dissipated irreversibly in the chemical reaction austenite (at interface) to pearlite as in the associated diffusion process, then

$$a = S_p$$

There is no reason however for making this assumption, because a is a well-defined parameter that is independent of such assumptions. Specifically,

$$a = \frac{L_d}{L_1} + \frac{L_d}{L_2}$$

where L_d is the mobility for the diffusion process; L_1 , the mobility for the reaction austenite (at interface) to ferrite; and L_2 , the mobility for the reaction austenite (at interface) to cementite.

Thus, the parameter a to a good approximation is exponentially dependent on temperature through an activation energy term, i.e., $\exp(-Q/RT)$, where Q , the activation energy, is equal to the activation energy for diffusion of carbon in austenite less the

activation energy for the reaction austenite at interface to ferrite. (The assumption is made here that the activation energy for either chemical reaction is about the same.) Thus, the temperature dependence of the interlamellar spacing may be either that suggested by Zener¹⁴ if the second term of Eq. II-12 is small compared to the first or that found by Mehl¹⁵ if the first term is small compared to the second term.

Because the interlamellar spacing is a function of the free energy dissipated in the transformation, the velocity of motion of the interface in this case is not simply proportional to the free energy dissipated per unit advance of the interface, see Eq. II-11. Thus, the simple statement that the motion of an interface is proportional to the free energy released per unit advance of the interface is not always equivalent to results derived from the thermodynamic theory of irreversible processes; see also the results of the last section.

Theory Applied to Plastic Deformation

Growth of a Dislocation Ring: Consider that at its inception a dislocation ring defines a circular region in a plane across which shear stress has been relaxed. The ring itself comprises the interface region. There is a linear tension τ associated with the ring equivalent to the surface tension associated with a grain boundary. The tension of a ring comprising a single dislocation singular line, for example, is approximately given by

$$\frac{Gd}{2\pi} \ln R/2d \text{ ergs per cm}$$

where G is the modulus of rigidity; d , the atomic spacing; and R , the radius of ring.

Instead of using Eq. I-6 for this problem, the fundamental Eq. I-4 may be employed. The rate of decrease of free energy is simply the rate of performing work on the specimen less the rate of storing energy in the ring. Analytically, this relationship is

$$\frac{dG}{dt} = -F \frac{dl}{dt} + \tau \frac{dR}{dt} = -\sigma A_s \frac{dl}{dt} + \tau \frac{dR}{dt}$$

where F is the applied tensile load; σ , the applied tensile stress; and A_s , the cross-sectional area of specimen. In this case, it is assumed that only one dislocation ring is growing and that there are no other contributions of plastic origin to the lengthening of a specimen pulled in uniaxial tension. Further it is assumed that

$$\frac{dl}{dt} \sim \frac{d(\pi R^2)}{dt}$$

(i.e., an increase in length is due to a proportional increase in the area across which slip has occurred). Also, it is desired to calculate the entropy production per unit length of ring. Using the DeDonder relation,

$$\frac{d_i s_l}{dt} = \frac{1}{T} (C_1 \sigma - \tau/2\pi R) \frac{dR}{dt}$$

Using Eq. I-2 and assuming the thermodynamic theory to apply to this case, then

$$\frac{dR}{dt} = \frac{L}{T} (C_1 \sigma - \tau/2\pi R) \quad [\text{II-14}]$$

This equation is limited to the situation where σ

times the volume per atom is less than kT . For $\sigma = 10,000$ psi, then the temperature range where Eq. II-14 is applicable is above about 1000°C . This equation should be equally applicable to the rate of growth of a slip band. Unfortunately only indirect methods are available to check this result and these methods do not yield definitive answers.

"Slipless" Flow: The irreversible process of slipless flow investigated recently by Udin and associates¹⁸ can be treated by this theory. Herring¹⁷ has already given one treatment based on the flow of vacancies under a chemical potential gradient, an alternate and equivalent treatment makes use of Eqs. I-2 and I-1. Using the DeDonder relation the rate of production of irreversible entropy per unit volume of specimen is

$$\frac{d_i s}{dt} = \left\{ \frac{W - \pi R (\gamma_s - \gamma_b R N/L)}{\pi R^2 L} \right\} \frac{dl}{dt} = \sigma \frac{d\epsilon}{dt}$$

where W is the external force on specimen; γ_s , the surface free energy per unit area; γ_b , the interface free energy per unit area; R , the radius of specimen; L , the gage length of specimen; N , the number of grain boundaries in length L ; σ , $\frac{W - \pi R (\gamma_s - \gamma_b R N/L)}{\pi R^2}$ = "apparent" stress; and

$d\epsilon = dL/L$ = natural strain. The limitation that σ times the volume per atom be much less than kT is obeyed for the experiments of Udin. Hence, by the assumption of the thermodynamic theory

$$\frac{d\epsilon}{dt} = L_s \sigma \quad \text{[II-15]}$$

where L_s is the mobility related to the migration of vacancies. These results are the same as those already derived by Herring¹⁸ and checked by Udin.

Recovery: For the phenomenon of recovery occurring uniformly over a macroscopic volume, the thermodynamic theory states that the rate of approach to equilibrium is proportional to the deviation from equilibrium. The appropriate state variable for recovery is the average[‡] internal strain,

[‡] Root-mean-square average is more appropriate than the arithmetic average which equals zero.

hence

$$\frac{d\epsilon}{dt} = -L\epsilon \quad \text{[II-16]}$$

This equation is checked by experience with recovery phenomena¹⁸ where the limitation that the average internal stress times the volume per atom is less than the thermal energy, kT , is obeyed.

Discussion of Results

The fact that many of the irreversible processes that interest metallurgists are within the scope of the thermodynamic theory of irreversible processes is fortunate, because the theory is very useful in providing a brief and general method of classifying diverse rate phenomena. If nothing else is obtained from the application of the theory, the pedagogic advantage of having a simple analytic description of growth phenomena justifies its consideration. The analytic description in one equation of nucleus growth during primary recrystallization, secondary recrystallization, and grain boundary migration is a case in point.

The fact that a wide variety of irreversible phenomena falls within the limitations of the theory

should stimulate a search for still other irreversible processes that may be so characterized and, more important, it should stimulate experimentation in the fields of interaction effects, such as thermal diffusion (diffusion due to a temperature gradient, boundary migration due to diffusion across the boundary, etc.). With respect to the latter suggestion the reader is cautioned to read DeGroot,¹ for there are limitations to the theory which should be understood. One such limitation is that no interactions in the sense of the theory would be expected to occur between a scalar flux, such as recovery, and a vector flux, such as diffusion.

A discussion of the assumptions involved in the method used to derive the rate of interface motion is in order. The unique assumptions of this method were: 1—that the production of irreversible entropy was confined mainly to the interface region, hence, by analogy with the theory as previously developed, the specific irreversible entropy production per unit area of this interface region would be quadratic in the "forces" causing motion of the interface region, and 2—that the irreversible entropy was uniformly produced over the unit area of interface considered. Whenever two fluxes of different tensor rank are involved in the interface motion, the statement that the velocity of interface motion is proportional to the free energy released per unit advance of the interface must be examined carefully. For example, in the pearlite transformation the velocity of growth is not simply proportional to the free energy released per unit advance, but is a more complex function of the dissipated energy. Finally, the theory should be applied only to those cases where the free energy released per mol traversed is less than RT .

This mode of description of boundary migration has an interesting implication; namely, that the phenomenological equations can be made mechanism-sensitive by describing the mode of nonuniform entropy production. For example, in the growth of a crystal from the vapor, there are at least two mechanisms of growth which can be considered. These mechanisms are uniform deposition on the surface at high saturation of the vapor phase and preferred deposition on the spirals emanating from screw dislocations at low saturation. In the former case the growth law is given by Eq. I-6, in the latter case a spiral migration rate must be calculated on the basis of an interface localized at the spiral: the irreversible entropy production is localized to lie in some region adjacent to the spiral. (Incidentally, the expression obtained for the rate of migration of the spiral normal to itself is proportional to the right hand side of Eq. I-6.) Then the rate of growth of the crystal must be expressed in terms of the rate of advance of the spirals. Thus, the theory will give correct results, if it is applicable to the microscopic processes that occur, and if the particular mode of nonuniform entropy production ("plane" interface of constant or varying thickness normal to the plane, "line" interface, etc.) is taken explicitly into account in the equations describing the phenomenon as it appears macroscopically. Another example illustrating this point is the process of sintering. Herring¹⁹ has considered the rate laws obtained for many different assumptions of the mechanism of sintering using the proper forces obtained from the thermodynamic theory in each case. This aspect of the mode of production of irreversible entropy must be considered in the process of applying the thermodynamic theory.

Fig. 1—Growth rate vs induction period for aluminum. Data from Anderson and Mehl.⁹

Finally, the significance of some of the results should be described here. First, it is apparent because of the correlation described in Fig. 1, that the incubation period in primary recrystallization is a consequence of slow growth and not of nucleation or transient nucleation. Second, it seems reasonable in view of the quantitative agreement obtained that the variation of the exponent in the grain growth law, $D = Kt^n$, is due to the migration of impurities along with the migration of the grain boundaries. This result is worth checking into further.

Summary and Conclusions

It is found that the thermodynamic theory of irreversible processes predicts that for many growth processes boundaries (interfaces) shall move at a rate proportional to the Gibbs free energy released per unit volume swept by the interface. However, this description is not generally true and each particular application must be considered separately in terms of the theory.

The equation applicable to growth in primary recrystallization, secondary recrystallization, or grain growth is

$$\frac{dR}{dt} = \frac{L_r}{T} \left(\Delta g_s + \Delta g_b - 2\sigma/R + \frac{\sum_i K_i}{R^3} \frac{\partial \sigma}{\partial C_i} \right)$$

where Δg_s is the difference in strain free energy across interface; Δg_b , the difference in free energy due to grain boundary area per unit volume on both sides of interface; σ , the interface energy per unit area; R , the radius of boundary; C_i , the concentration of i atoms in boundary; L_r , the mobility; T , the absolute temperature; K_i , a constant times number of i atoms migrating with grain boundaries; Δg_s is 0 for secondary recrystallization and grain growth;

Δg_b is 0 for grain growth; and $\sum_i \frac{K_i}{R^3} \frac{\partial \sigma}{\partial C_i} = 0$ for pure metals.

Three results derived from this equation should be emphasized: 1—the induction period in primary as well as secondary recrystallization is due to slow growth; 2—the grain growth law $D = Kt^{1/2}$ corre-

sponds to the case of impurities traveling with the boundaries such that $\partial \sigma / \partial C < 0$

$$\sum_i \frac{K_i}{R^3} \frac{\partial \sigma}{\partial C_i} >> 2\sigma/R$$

and 3—a limitation to grain growth due to impurities at the boundary is predicted for the case where $\partial \sigma / \partial C > 0$.

An interesting interaction effect is predicted between boundary migration and diffusion across the boundary, or heat and electrical flows across the boundary.

The equation applicable to the growth of spherical particles in a superheated or supercooled one component matrix is

$$\frac{dR}{dt} = \frac{L_o}{T} (\Delta g - 2\sigma/R)$$

where the terms have the same significance as for the previous case.

The equation applicable to the growth of a spherical particle of one stable phase in a supersaturated matrix is

$$\frac{dR}{dt} = K/t^{1/2}$$

where K is a function of chemical potentials and concentrations (see text), and t is time. The other terms have the same significance as before. The equations applicable to the growth of pearlite are

$$V = \frac{L_p}{T} \frac{(\Delta g - 2\sigma'/S_p^*)}{(a + S_p^*)}$$

and

$$S_p^* = 4\sigma'/\Delta g + a/2$$

where V is the velocity of growth; σ' , the ferrite-cementite interface energy; S_p^* , the interlamellar spacing corresponding to maximum rate of growth; and a , the sum of ratios of mobilities (see text) which is exponentially dependent on the reciprocal of the absolute temperature. These equations are obtained by considering that not only does diffusion occur but also a chemical reaction occurs. These two processes are complementary—neither is the limiting process because the boundary conditions for one are controlled by the other.

The rate of propagation of a slip band is also treated in the text with the following result:

$$\frac{dR}{dt} = \frac{L_s}{T} (C\sigma - \tau/2\pi R)$$

where σ is the applied stress, and τ , the linear tension at spearhead of slipped region.

The relation between flux and force given by the theory for a uniform approach to equilibrium in the specimen is that the rate of change of some state parameter is proportional to the partial derivative of the Gibbs free energy with respect to the conjugate state parameter. In simple words, the rate of approach to equilibrium is proportional to the deviation from equilibrium. An example of this relation is found for recovery where

$$\frac{d\epsilon}{dt} = -\frac{L}{T} \epsilon$$

Here ϵ is some average internal strain. A description of slipless flow alternate to that of Herring is also given in the text. Almost all the processes

treated are specialized examples of the general theory which treats the case of more than one flux acting simultaneously.

The situation described by a continuous variation of a state parameter has not been treated in this paper because of adequate coverage elsewhere. In this case, the "force" is a gradient of a thermodynamic potential such as chemical potential, temperature, pressure, etc.

The conclusion is made that a multitude of irreversible phenomena studied in metallurgy are described by the language of the thermodynamic theory of irreversible processes. For all these processes the limitation of the theory to processes where the driving energy per atom is less than the thermal energy, kT , is obeyed.

Technical Note

Grain Boundary Films in Boron Steels

by J. W. Spretnak and Rudolph Speiser

IT has been suggested that boron in steel may form a film entirely around the austenite grain and that this film is responsible for the boron hardenability effect. In this connection, it is of interest to examine some of the ramifications of the concentration range of boron usually employed in hardenable steels, namely 0.0005 to 0.003 pct in a grain size range of ASTM grain size No. 1 through No. 10.

The ratio of the iron to boron atoms and the number of unit cells of γ iron per boron atom are listed in Table I. Even at the highest concentration considered, there are 1600 unit cells of γ iron per boron atom, assuming a uniform distribution of boron.

To investigate the possibility of the boron film formation, the number of boron atoms required to cover the grain surface completely must be calculated. With some transition elements, boron crystallizes in sheets composed of equilateral hexagons very much like graphite.¹ The selected value for the length of a side is 1.80Å. A simple calculation shows that two boron atoms cover an area of 8.4×10^{-18} sq cm. Table II lists the number of atoms of boron required for the formation of the monatomic film and Table III lists the number of boron atoms per grain.

J. W. SPRETNAK, Member AIME, and R. SPEISER are Associate Professors, Dept. of Metallurgy, Ohio State University, Columbus, Ohio.

TN 150E. Manuscript, Nov. 28, 1952.

This work on the boron hardenability effect is sponsored by The Office of Flight Research under Contract No. AF 18(600)-94.

The hypothetical cases of 100 pct and 10 pct adsorption are calculated (all boron atoms in a grain and 10 pct of all boron atoms in a grain are located at the grain surface respectively). In Table III, all combinations of grain size and composition below and to the left of the solid line (100 pct adsorption) and the dashed line (10 pct adsorption) are excluded as to the possibility of covering the grain surface with a continuous boron film. Thus, even for 100 pct adsorption, the smaller grains can form the film only at the higher concentrations. For the best case, grain size No. 1 and 0.0030 pct B, the required degree of adsorption is 3.9 pct.

The above calculations deal only with the number of boron atoms required to form a monatomic film and do not take into account the mechanism of concentration of boron at the grain surface and the possible limitations to the extent of this concentration at a constant temperature, as for example in the austenitizing process. The question next arises as to how this surface concentration can occur during an isothermal treatment. Such surface enrichment of boron must occur through the phenomenon of surface adsorption, i.e., the concentration of solute atoms in solid solution in the vicinity of the surface without precipitation. A solute atom will tend to concentrate at the grain boundary if it reduces the interfacial tension. The possibility of adsorption effects involving both boron and carbon in iron has been discussed.² In general, the tendency for a sol-

boron in the region of the grain surface at this constant temperature is limited to this concentration. The thickness of the surface phase enriched by adsorption is not known. Assuming grain size No. 6 and that the adsorption effect is limited to a surface shell ten unit cells thick, the maximum possible adsorption for an average concentration of 0.005 pct B is 0.25 pct† for isolated grains and 0.50 pct for con-

† The number of unit cells in the shell is 0.61×10^{12} , which at saturation would contain 3.67×10^8 boron atoms. A single grain contains 1.46×10^{11} boron atoms. Therefore the percent adsorption is $(3.67 \times 10^8 \div 1.46 \times 10^{11}) 100$.

tiguous grains. From Table III, essentially 100 pct adsorption is required to form the film in this case. Considering only the surface layer of atoms enriched by adsorption, this amounts to 0.01 pct adsorption‡ for isolated grains and 0.02 pct for con-

‡ Each cell face at the surface has two iron atoms. The number of boron atoms is at saturation $2(0.609 \times 10^{11}) = 0.1832 \times 10^8$; the percent adsorption is $(0.1832 \times 10^8 \div 6.65 \times 10^8) 100 = 0.01$.

tiguous grains. Thus, from the above arguments, it is extremely unlikely that continuous or extended boron films form on austenite grain surfaces and are responsible for the hardenability effect. It is evi-

ute atom to concentrate at the grain boundary would be expected to increase with an increase in temperature. Since adsorption is concentration in solid solution without precipitation, the limitation to the extent of concentration at a particular temperature is the solubility of the solute atom at this temperature. Any further concentration of boron would require the precipitation of the compound Fe_2B from solid solution. The precipitation of this compound would require that the solid solution become supersaturated with respect to boron. This supersaturation cannot occur by the adsorption mechanism at constant temperature, and such precipitation usually occurs on reducing the temperature with resulting decrease in solubility. The only possibility of precipitation at constant temperature is the case in which a second solute element such as carbon is present and also undergoes grain boundary adsorption along with boron. Thus the solubility product for boron carbide in iron could be exceeded at the grain boundary without exceeding the solubility limit of either solute atom. Such precipitation would deplete the solid solution at the grain boundary and allow further adsorption to take place.

The solubility of boron in γ iron is estimated to

dent that the distribution of boron and Fe_2B precipitates at the grain boundary will be localized and spotty.

Although it is quite unlikely that a grain boundary film is the underlying boron hardenability mechanism, the possibility of adsorption effects involving boron in solid solution in austenite appears to be of primary importance in explaining some aspects of the boron hardenability effect. For example, the metallographic test for boron⁸ and the optimum austenitizing range^{3,4} for boron steels can be rationalized in terms of adsorption effects.

Measurement of Particle Sizes in Opaque Bodies

by R. L. Fullman

IN the investigation of metallurgical transformations and the relationships between microstructure and properties of metals, it frequently is desirable to obtain a measurement of the relative amounts of the various phases present and of the mean size of particles into which each phase is dispersed. The relative amounts of the phases can be measured by the classical methods of area, lineal, and point analysis,¹⁻⁵ in accordance with the principle that the volume fraction of a phase, the fraction of a polished cross section occupied by the phase, the fraction of a random line occupied by the phase, and the fraction of randomly arrayed points occupied by the phase are all equal. The validity of this relationship depends only on the attainment of a truly random sample of area, length, or points, and not on the size, shape, or distribution of the particles constituting the phase. Smith and Guttman⁶ have derived a relationship between the interface area per unit volume S_v and the measurable quantities L_s , the interface length per unit area on a cross section, and N_L , the number of interfaces per unit length intersected by a random line. Their equation,

$$S_v = \frac{4}{\pi} L_s = 2N_L$$

is also valid regardless of the distribution of particle sizes and shapes.

In contrast to the situation concerning measurement of relative fractions of phases and of interface area, the measurement of particle sizes in opaque samples has not been subjected to a complete analysis. It has been common to measure some lineal or area dimension of particles on a polished cross section and to use the mean value as a qualitative measure of particle size. In the present paper, quantitative relationships are established among the various mean dimensions on a polished cross section and the actual dimensions of the particles present.

Particles of Uniform Size

Spheres: If a metal sample contains particles of a phase α dispersed in the form of spheres of uniform size, a polished cross section through the sample will reveal circular areas of phase α with radii from 0 to r , the radius of the spheres. Consider a cube of unit dimensions to be cut from the sample. If a cross section parallel to one of the cube faces is examined, the average number of particles per unit area (N_s) equals the number of particles per unit volume (N_v) times the probability p_1 that the plane would intersect a single sphere positioned at random within the unit cube. Since, of the various possible positions for the cross-sectional plane over the unit length from top to bottom of the cube, only those positions existing over the length $2r$ would lead to the plane intersecting the sphere, the probability of intersecting a single sphere is just $2r$.

R. L. FULLMAN, Junior Member AIME, is associated with the Research Laboratory, General Electric Co., Schenectady.

Discussion on this paper, TP 3432E, may be sent, 2 copies, to AIME by Dec. 1, 1953. Manuscript, April 8, 1952. Cleveland Meeting, October 1953.

$$N_s = N_v p_1 = N_v \cdot 2r \quad [1]$$

Applying the equality of area and volume fractions, the relationship is found between sphere size and average area \bar{s} of uniform spheres intersected by a random cross section,

$$f = N_v V = N_v \cdot \frac{4}{3} \pi r^3 = N_s \bar{s} = N_v \cdot 2r \bar{s} \\ \bar{s} = \frac{2}{3} \pi r^2 \quad [2]$$

A similar analysis reveals the average traverse length across spheres of uniform size when random lines are passed through the sample. If a randomly oriented unit cube is cut from the sample and a randomly positioned line is passed through the cube parallel to a cube edge, the number of spheres intersected by the line (N_L) equals the number of spheres per unit volume times the probability p_1 of the line hitting a single randomly placed sphere in the cube. Since possible positions of the line occupy unit area, and possible positions for which it will pass through the sphere occupy an area of πr^2 , the probability of the line hitting a randomly placed single sphere is πr^2 .

$$N_L = N_v p_1 = N_v \pi r^2 \quad [3]$$

Combining this relationship with the equality of volume and lineal fraction, the desired relationship is obtained between radius and mean lineal traverse length \bar{l} , for spheres of uniform size.

$$f = N_v V = N_v \cdot \frac{4}{3} \pi r^3 = N_L \bar{l} = N_v \cdot \pi r^2 \bar{l} \\ \bar{l} = \frac{4}{3} r \quad [4]$$

Circular Plates: Consider a sample containing particles of a phase α in the form of circular plates of uniform radius r and thickness t , where $r \gg t$. If the plates are randomly oriented, as in a sufficiently large sample of a fine grained polycrystalline material, area and lineal analysis may be carried out with parallel cross-sectional planes and lineal traverses. If the plates are not randomly oriented, it is necessary to randomize the orientation of the cross-sectional planes and traverse directions. Let a unit cube be cut from the sample, and a cross-section plane be passed through the cube parallel to one of the cube faces. The number of plates cut by the cross-sectional plane per unit area is equal to the number of plates per unit volume times the probability of a plate intersecting a single randomly positioned and randomly oriented plate in the cube. If J is the component of the plate diameter in the direction normal to the cross-sectional planes, the probability of a plane cutting a single randomly oriented plate is equal to \bar{J} , the mean value of J for all possible orientations of the plate.

Let ϕ be the dihedral angle between a plate and the cross-sectional plane, and let $p_\phi d\phi$ be the probability that a plate makes an angle between ϕ and $\phi + d\phi$ with the cross-sectional plane. Then for ran-

Fig. 1—Intersections of a circular plate in a unit cube with (a) a cross-sectioning plane and with (b) a lineal traverse.

domly oriented plates, $p_\phi = \sin \phi$. Let $p_J dJ$ be the probability that a given plate has a diameter component perpendicular to the cross-sectional plane between J and $J + dJ$. Referring to Fig. 1a,

$$J = 2r \sin \phi$$

$$p_J = p_\phi \left| \frac{d\phi}{dJ} \right| = \frac{\tan \phi}{2r}$$

The average value of J for all orientations is equal to the integral, over all possible values of J , of the product of J and its probability.

$$\bar{J} = \int_0^{2r} J p_J dJ = \frac{\pi}{2} r$$

$$N_s = \bar{J} N_v = \frac{\pi}{2} r N_v \quad [5]$$

Combining Eq. 5 and the equality of volume and area fraction, the desired relationship is obtained between plate size and average area of particles intersected by a random cross section.

$$f = N_v V = N_v \pi r^2 t = N_s \bar{s} = \frac{\pi r^2}{2} N_v \bar{s} \quad [6]$$

$$\bar{s} = 2rt$$

If random lines parallel to an edge of the unit cube are passed through a sample, the number of plates per unit length intersected by the lines is equal to the number of plates per unit volume times the probability that a line will intersect a single randomly positioned and randomly oriented plate in the cube. If a is the apparent area of a plate as viewed from the direction of the lines, the probability of a line cutting a single randomly positioned and oriented plate is equal to the mean value of a , averaged over all possible plate orientations. If ϕ is the angle between the lineal traverses and the normal to a plate, this angle is completely equivalent to that defined above, with respect to its probability of existence. Referring to Fig. 1b,

$$a = \pi r^2 \cos \phi$$

$$p_a = p_\phi \left| \frac{d\phi}{da} \right| = \frac{1}{\pi r^2}$$

Again integrating to find the mean value of the apparent area, \bar{a} , the result is

$$\bar{a} = \int_0^{\pi r^2} a p_a da = \frac{1}{\pi r^2} \int_0^{\pi r^2} a da = \frac{\pi r^2}{2}$$

$$N_L = \bar{a} N_v = \frac{\pi r^2}{2} N_v \quad [7]$$

Combining Eq. 7 with the equality of volume and lineal fractions, the desired value is obtained of the mean traverse length \bar{l} for plates of uniform size.

$$f = N_v V = N_v \pi r^2 t = N_L \bar{l} = N_v \frac{\pi r^2}{2} \bar{l}$$

$$\bar{l} = 2t \quad [8]$$

Rods: Consider a sample containing a phase α in the form of randomly oriented rods of radius r and length H , where $H \gg r$. A unit cube cut from the sample is cut by a plane parallel to a cube face. Let J be the component of rod length in the direction normal to the cross-section planes. Then the number of rods per unit area on the cross section is equal to the number of rods per unit volume times the probability that a single randomly positioned and oriented rod is cut by a plane. Hence, the number per unit area is equal to the number per unit volume times the mean value of J , averaged over all rod orientations. Let ϕ be the angle between a rod and the direction perpendicular to the cross-section planes. Referring to Fig. 2a,

$$J = H \cos \phi$$

p_ϕ is again equal to $\sin \phi$, so that

$$p_J = p_\phi \left| \frac{d\phi}{dJ} \right| = \frac{1}{H}$$

$$\bar{J} = \int_0^H J p_J dJ = \int_0^H \frac{J}{H} dJ = \frac{H}{2}$$

$$N_s = N_v \bar{J} = \frac{N_v H}{2} \quad [9]$$

Combining Eq. 9 with the equality of volume and area fractions, the desired value is found of the mean area of rods intersected by a random cross section.

$$f = N_v V = N_v \pi r^2 H = N_s \bar{s} = \frac{N_v H}{2} \bar{s}$$

$$\bar{s} = 2\pi r^2 \quad [10]$$

If straight lines are passed through the unit cube parallel to one of the cube edges, the number of rods per unit length intersected along the line is equal to the number per unit volume times the probability p_1 that a single line hits a single randomly positioned and oriented rod. The latter probability is equal to the average area \bar{a} presented by randomly oriented rods viewed from the direction of the lines. Let ϕ be the angle between the axis of a rod and the direction of the lines. Then, referring to Fig. 2b,

$$a = 2rH \sin \phi$$

p_ϕ is again equal to $\sin \phi$, so that

$$p_\phi = p_\phi \left| \frac{d\phi}{da} \right| = \frac{\tan \phi}{2rH}$$

$$\bar{a} = \int_0^{2rH} a p_\phi da = 2rH \int_0^{\pi/2} \sin^2 \phi d\phi = \frac{\pi rH}{2}$$

$$N_L = \bar{a} N_v = \frac{\pi rH}{2} N_v \quad [11]$$

Combining Eq. 11 and the equality of lineal and volume fractions, the desired value of the mean lineal traverse across randomly oriented rods of uniform size is found.

$$f = N_v V = N_v \pi r^2 H = N_L \bar{l} = \frac{\pi rH}{2} N_v \bar{l} \quad [12]$$

$$\bar{l} = 2r$$

Note that neither the average cross-sectional area nor the average lineal traverse of particles in the form of long thin rods depends on the length of the rods. It does not appear possible to measure the length of particles in this shape by any of the usual measurements on polished cross sections. This fact demonstrates immediately the impossibility of finding a relationship between measured quantities and any sort of "average particle dimension" that would apply regardless of particle shape.

Combinations of Point, Lineal, and Area Analysis for Particles of Uniform Size: While the measurement of average lineal traverse or average particle area sectioned is sufficient to describe the particle size, as shown in the preceding sections, some other simple relationships may be established which are useful in that they sometimes permit the use of simpler experimental methods. For example, combining Eqs. 1 and 3, the result is

$$r = \frac{2}{\pi} \frac{N_L}{N_s} \quad [13]$$

This relationship permits measuring the radius of uniform spheres by merely counting the number of spheres intersected per unit length of traverse and the number of spheres intersected per unit area of cross section. The necessity for actually measuring either lineal traverse lengths or areas intersected on the cross section is eliminated. For the special instance of grain size measurement, where the volume fraction equals 1, either count alone is sufficient. Then

$$r = \frac{3}{4N_L} = \sqrt{\frac{3}{2\pi N_s}} \quad [14]$$

Eqs. 1 and 3 may also be combined to yield the number of particles per unit volume

$$N_v = \frac{\pi}{4} \frac{N_s^2}{N_L} \quad [15]$$

or to provide a means of measuring the volume fraction of a phase dispersed as uniform spheres.

$$f = \frac{8}{3\pi} \frac{N_L^2}{N_s} \quad [16]$$

For circular plates, Eqs. 5 and 7 may be combined to permit measurement of several quantities of interest.

$$r = \frac{N_L}{N_s} \quad [17]$$

$$t = \frac{f}{2N_L} \quad [18]$$

$$N_v = \frac{2}{\pi} \frac{N_s^2}{N_L} \quad [19]$$

For rods a similar combination of Eqs. 9 and 11 leads to the following relationships:

$$r = \frac{1}{\pi} \frac{N_L}{N_s} \quad [20]$$

$$f = \frac{2}{\pi} \frac{N_L^2}{N_s} \quad [21]$$

Another quantity of frequent interest in quantitative metallography is the mean free path between

Fig. 2—Intersections of a rod in a unit cube with (a) a cross-sectioning plane and with (b) a lineal traverse.

Fig. 3—Intersection of a sphere with a cross-sectioning plane.

particles. The mean free path P may always be found from the relationship

$$P = \frac{1-f}{N_L} \quad [22]$$

which is valid regardless of the shape or distribution of sizes of the particles. Other measures of the mean free path may be obtained by combinations of the relations already found for particles of uniform size and shape, but these do not appear to offer any significant advantage over the general formula.

Particle Size in Samples with Nonuniform Size Particles

The simple relationships developed in the previous section apply precisely only if the particle size is uniform, but they may be used for approximate measurements provided that the range of particle sizes is small. If more accurate measurements are desired, or if there is a large range of particle sizes, the variation in particle size must be taken into account. The necessary analysis for determining the complete distribution of particle sizes present when the particles are in the form of spheres has been carried out by Hagermann,⁷ Scheil and coworkers,⁸⁻¹⁰ and Huber.¹¹ The equations presented above for plates and rods may be combined with the general methods of approach used by these authors to develop methods for measurement of the complete distribution of particle size for these shapes as well. However, the measurement of mean particle sizes for samples containing a distribution of sizes can be measured more easily than the complete distribution function, and these mean values frequently provide an adequate description of the structure. For example, a complete description of the kinetics of a transformation occurring by nucleation and growth is obtained if the number of particles per unit volume, as well as the volume fraction occupied by a new phase, is determined as a function of the transformation time and temperature.

Spheres: Consider a sample containing particles of a phase α in the form of spheres of various radii. If the particles are divided into groups according to their radius, then for each group with radius arbitrarily close to some value r_i , equations analogous to Eqs. 1 to 4 may be written

$$N_{s_i} = 2r_i N_{v_i} \quad [1a]$$

$$\bar{s}_i = \frac{2}{3} \pi r_i^2 \quad [2a]$$

$$N_{L_i} = \pi r_i^2 N_{v_i} \quad [3a]$$

$$\bar{l}_i = \frac{4}{3} r_i \quad [4a]$$

Combining these relationships and summing over all values of the radius r_i , the following expressions for \bar{s} and \bar{l} are obtained:

$$\bar{s} = \frac{\sum_i N_{s_i} \bar{s}_i}{\sum_i N_{s_i}} = \frac{\sum_i N_{v_i} V_i}{2 \sum_i N_{v_i} r_i} = \frac{\bar{V}}{2 \bar{r}} \quad [23]$$

$$\bar{l} = \frac{\sum_i N_{L_i} \bar{l}_i}{\sum_i N_{L_i}} = \frac{\sum_i N_{v_i} V_i}{\pi \sum_i N_{v_i} r_i^2} = \frac{4 \bar{V}}{\bar{A}} \quad [24]$$

where \bar{A} is the average surface area of the spheres.

In order to separate the mean values of r , A , and V from Eqs. 23 and 24, it is necessary to add a new measurement. Let m_i be the reciprocal of the diameter of the circle of intersection of a sphere of radius r_i with a cross-section plane. Then, referring to Fig. 3,

$$m_i = \frac{1}{2 \sqrt{r_i^2 - x^2}}$$

where x is the distance of the cross-section plane from the center of the sphere. If $p_x dx$ is the probability that a cross-section plane cuts a sphere of radius r_i at a distance x to $x + dx$ from its center, then

$$p_x = \frac{1}{r_i}$$

If $p_{m_i} dm_i$ is the probability of finding a reciprocal diameter between m_i and $m_i + dm_i$,

$$p_{m_i} = p_x \left| \frac{dx}{dm_i} \right| = \frac{1}{2 m_i^2 r_i \sqrt{4 m_i^2 r_i^2 - 1}}$$

The mean value of m_i is equal to the integral, over all possible values of m_i , of its value times the probability of its existence at that value.

$$\bar{m}_i = \int_{\frac{1}{2r_i}}^{\infty} m_i p_{m_i} dm_i = \frac{\pi}{4 r_i}$$

Summing these mean values of \bar{m}_i over all sphere sizes and dividing by the total number of observations, an expression is obtained for the mean value \bar{m} for the whole sample.

$$\bar{m} = \frac{\sum_i N_{s_i} \bar{m}_i}{\sum_i N_{s_i}} = \frac{\pi \sum_i N_{v_i}}{4 \sum_i N_{v_i} r_i} = \frac{\pi}{4 \bar{r}} \quad [25]$$

Combining Eq. 25 with Eqs. 23 and 24, the necessary relationships between various mean dimension descriptions of the spheres and the several measurable quantities \bar{l} , \bar{s} , \bar{m} , and f are obtained.

$$\bar{r} = \frac{\pi}{4 \bar{m}} \quad [26]$$

$$\bar{V} = \frac{\pi \bar{s}}{2 \bar{m}} = \frac{\pi f}{2 \bar{m} N_s} \quad [27]$$

$$\bar{A} = \frac{2 \pi \bar{s}}{\bar{m} \bar{l}} = \frac{2 \pi N_L}{\bar{m} N_s} \quad [28]$$

$$N_v = \frac{2 \bar{m} f}{\pi \bar{s}} = \frac{2 \bar{m} N_s}{\pi} \quad [29]$$

Circular Plates: When the particles under consideration are in the form of circular plates with a

distribution of radius r and thickness t , this distribution may be divided into a number of arbitrarily small ranges of particles of radius r_i and within each such range of radii the plates may be further subdivided into arbitrarily small ranges of thickness t_j . Then for each range of particle size, equations equivalent to Eqs. 5 to 8 may be written.

$$N_{s_{ij}} = \frac{N_{v_{ij}} V_{ij}}{\bar{s}_{ij}} = \frac{\pi}{2} N_{v_{ij}} r_i \quad [5a]$$

$$\bar{s}_{ij} = 2 r_i t_j \quad [6a]$$

$$N_{L_{ij}} = \frac{N_{v_{ij}} V_{ij}}{\bar{l}_{ij}} = \frac{\pi}{2} N_{v_{ij}} r_i^2 \quad [7a]$$

$$\bar{l}_{ij} = 2 t_j \quad [8a]$$

Adding the contributions of all particle size ranges to the total number per unit area and per unit length observed, the following is obtained:

$$\frac{\bar{s}}{s} = \frac{\sum_i \sum_j N_{L_{ij}} \bar{l}_{ij}}{\sum_i \sum_j N_{s_{ij}}} = \frac{2 \sum_i \sum_j N_{v_{ij}} V_{ij}}{\pi \sum_i \sum_j N_{v_{ij}} r_i} = \frac{2 \bar{V}}{\pi \bar{r}} \quad [30]$$

$$\bar{l} = \frac{\sum_i \sum_j N_{L_{ij}} \bar{l}_{ij}}{\sum_i \sum_j N_{L_{ij}}} = \frac{2 \sum_i \sum_j N_{v_{ij}} V_{ij}}{\pi \sum_i \sum_j N_{v_{ij}} r_i^2} = \frac{4 \bar{V}}{\bar{A}} \quad [31]$$

In order to separate the various mean dimensions from these equations, and in order to find a measure of the mean plate thickness, it is necessary to introduce three more measurable quantities.

Let E be the reciprocal of the length of intersection of a plate with a cross-sectioning plane. Then referring to Fig. 4,

$$E_i = \frac{1}{2 \sqrt{r_i^2 - x^2}}$$

where x is the distance from the center of the plate to its intersection with the cross-sectioning plane. If $p_s dx$ is the probability that the plate is intersected by the cross-sectioning plane at a distance between x and $x + dx$ then

$$p_s = \frac{1}{r_i}$$

Let $p_{E_i} dE_i$ be the probability that the reciprocal of the intersection length lies between E_i and $E_i + dE_i$. Then

$$p_{E_i} = p_s \left| \frac{dx}{dE_i} \right| = \frac{(r_i^2 - x^2)^{3/2}}{r_i x}$$

The mean value of E_i is equal to the integral of the product of E_i and the probability of its existence, over all possible values of E_i .

$$\bar{E}_i = \int_{\frac{1}{2r_i}}^{\infty} E_i p_{E_i} dE_i = \frac{\pi}{4 r_i}$$

Summing the values of \bar{E}_i over all values of the plate radius r_i the following is obtained:

$$\bar{E} = \frac{\sum_i N_{s_i} \bar{E}_i}{\sum_i N_{s_i}} = \frac{\pi \sum_i N_{v_i}}{4 \sum_i N_{v_i} r_i} = \frac{\pi}{4 \bar{r}} \quad [32]$$

In order to find a measure of the average plate thickness, a quantity F is defined as the reciprocal of the width of an intersection of a plate with a cross-sectioning plane. Then, referring to Fig. 4, if

Fig. 4—Intersection of a circular plate with a cross-sectioning plane.

ϕ is the dihedral angle between the plate and the cross-sectioning plane,

$$F_{ij} = \frac{\sin \phi}{t_j}$$

In the present instance the probability function of ϕ required is the probability of cutting a plate at angle ϕ with the cross-sectioning plane, so that it is the probability that a plate lies at an angle ϕ with the sectioning plane times the probability that a plate lying at this angle will be cut by the plane. Since both of these probabilities are proportional to $\sin \phi$,

$$p_\phi = K \sin^2 \phi$$

If $p_{F_{ij}} dF_{ij}$ is the probability that the reciprocal of cross-section width lies between F_{ij} and $F_{ij} + dF_{ij}$, its value is

$$p_{F_{ij}} = p_\phi \left| \frac{d\phi}{dF_{ij}} \right| = K t_j \frac{\sin^2 \phi}{\cos \phi}$$

where the constant K may be evaluated from the fact that the sum of the probabilities of all possible values of F_{ij} must equal 1.

$$\int_0^{1/t_j} p_{F_{ij}} dF_{ij} = K \int_0^{\pi/2} \sin^2 \phi d\phi = \frac{\pi}{4} K = 1$$

Therefore,

$$p_{F_{ij}} = \frac{4}{\pi} t_j \frac{\sin^2 \phi}{\cos \phi}$$

The mean value of F_{ij} is equal to the integral, over all possible values of F_{ij} , of the product of F_{ij} and its probability.

$$\bar{F}_{ij} = \int_0^{1/t_j} F_{ij} p_{F_{ij}} dF_{ij} = \frac{4}{\pi t_j} \int_0^{\pi/2} \sin^3 \phi d\phi = \frac{8}{3 \pi t_j}$$

Summing the values of F_{ij} over all values of the plate radius and thickness and dividing by the number of observations of all plate sizes,

$$\bar{F} = \frac{\sum_i \sum_j N_{s_{ij}} \bar{F}_{ij}}{\sum_i \sum_j N_{s_{ij}}} = \frac{8 \sum_i \sum_j N_{v_{ij}} \frac{r_i}{t_j}}{3 \pi \sum_i \sum_j N_{v_{ij}} r_i} = \frac{8}{3 \pi} \frac{\left(\frac{\bar{r}}{\bar{t}} \right)}{\bar{r}} \quad [33]$$

If the ratio of radius to thickness of the plates is

independent of the plate radius, Eq. 33 provides a measure of the mean plate thickness, since, under these conditions,

$$\bar{F} = \frac{8}{3\pi t} \quad [33a]$$

However, if the radius-to-thickness ratio is not independent of plate size, the mean plate thickness may still be found by measurement of the ratio of width to length of intersections of plates with the cross-sectioning plane. Let G be this ratio; then

$$G_{ij} = \frac{t_j}{2 \sin \phi \sqrt{r_i^2 - x^2}}$$

where ϕ and x have the same meanings as previously. As before the probability functions for ϕ and x may be written as follows:

$$p_\phi = \frac{4}{\pi} \sin^2 \phi$$

$$p_x = \frac{1}{r_i}$$

In this case the probability function for G depends on both the probability functions of ϕ and x .

$$p_{G_{ij}} = \int_0^{\sqrt{r_i^2 - t_j^2/4G_{ij}^2}} p_\phi \left| \frac{\partial \phi}{\partial G_{ij}} \right| p_x dx = \frac{t_j^2}{2r_i^2 G_{ij}^3}$$

The mean value of G is equal to the integral, over all possible values of G , of the product of G and its probability.

$$\bar{G}_{ij} = \int_{t_j/2r_i}^{\infty} G_{ij} p_{G_{ij}} dG_{ij} = \frac{t_j}{r_i}$$

Summing over all plate sizes,

$$\bar{G} = \frac{\sum_i \sum_j N_{ij} \bar{G}_{ij}}{\sum_i \sum_j N_{ij}} = \frac{\sum_i \sum_j N_{ij} t_j}{\sum_i \sum_j N_{ij} r_i} = \frac{\bar{t}}{\bar{r}} \quad [34]$$

Combining Eqs. 30 to 34, the desired relationships between the mean values of plate dimensions and the mean values of the several measurable quantities are obtained.

$$\bar{r} = \frac{\pi}{4\bar{E}} \quad [35]$$

$$\bar{t} = \frac{\pi\bar{G}}{4\bar{E}} \quad [36]$$

$$\bar{V} = \frac{\pi^2 \bar{s}}{8\bar{E}} = \frac{\pi^2 f}{8\bar{E} N_s} \quad [37]$$

$$\bar{A} = \frac{\pi^2 \bar{s}}{2\bar{E} \bar{l}} = \frac{\pi^2 N_L}{2\bar{E} N_s} \quad [38]$$

$$N_v = \frac{8\bar{E} f}{\pi^2 \bar{s}} = \frac{8\bar{E} N_s}{\pi^2} \quad [39]$$

$$\left(\frac{\bar{r}}{\bar{t}} \right) = \frac{3\pi^2 \bar{F}}{32\bar{E}} \quad [40]$$

If the ratio of plate radius to thickness is independent of plate size,

$$\left(\frac{\bar{r}}{\bar{t}} \right) = \frac{\bar{r}}{\bar{t}}$$

so

$$\frac{1}{\bar{G}} = \frac{3\pi^2 \bar{F}}{32\bar{E}} \quad [41]$$

This relationship provides a means of checking on whether or not the radius-to-thickness ratio depends on plate size.

Rods: Since the analysis of rods, even of uniform size, does not permit separation of the rod length from the number of rods per unit volume, it does not appear profitable to pursue the analysis of rods of nonuniform size. Fortunately, most metallurgical transformations lead to the formation of particles in the form of either spheres or plates so that our inability to analyze the particle size of rod-shaped particles is not a serious limitation.

Summary

Methods have been developed for the analysis of particle size measurements by area and lineal analysis when the particles are in the form of spheres, plates, or rods. Methods that are valid when there is a wide range of particle sizes were developed, as well as simpler methods which apply when the particle size is uniform. It was shown that the usual types of observation do not permit measurement of the length of rod-shaped particles. For such particles there is a negligible probability that a cross-sectioning plane will cut along the rod length, so that statistical observations of the dimensions of intersections of the particles with a cross-sectioning plane depend only on the rod's radius. Despite this limitation, the method permits description of the distribution of phases present in commonly encountered metallurgical samples.

Effect of Various Elements on Hot-Working Characteristics And Physical Properties of Fe-C Alloys

by C. Travis Anderson, Robert W. Kimball, and Francis R. Cattoir

ONE of the principal impurities in all steels is sulphur. Sulphur-bearing, manganese-free steels exhibit hot shortness. Manganese is added to steel to improve the hot-working properties. If no sulphur were present in steel, it is probable that hot shortness would be nonexistent.

This paper is the first of a series to be issued by this Laboratory reporting the measurements of hot forgeability tests and the physical properties of Fe-C alloys to which additions of various alloying elements have been made. The present paper describes the results obtained by the addition of varying amounts of sulphur to Fe-C alloys.

To obtain control over residual elements in the various charges melted in the arc furnace, it was considered advantageous to use sponge iron from one source as the melting stock rather than scrap metal having an unknown history. Small amounts of unwanted alloying elements might be introduced into the charge when scrap was used, thereby influencing the results of the various heats.

A sponge iron having a high silica-lime ratio was used. Ore from Sunrise, Wyo., had been reduced to sponge iron and briquetted at the Bureau of Mines sponge-iron plant at Laramie, Wyo. The briquettes were 5 in. in diam and 2 to 3 in. in thickness, and weighed about 10 lb each. The chemical analysis of the sponge iron is as follows: C, 0.67 pct; Mn, 0.10; SiO₂, 4.75; CaO, 1.4; P, 0.044; S, 0.72; MgO, 0.4; Al₂O₃, 1.1; total Fe, 87.5; Fe metallic, 79.2; and reduction, 90.5 pct.

Where a reducing agent was required, crushed graphite electrodes usually were used. The charcoal available contained 0.20 pct S. An analysis of the available coke showed it to contain 0.70 pct S. Where high sulphur heats were required, elemental sulphur additions were made to the ladle.

Limestone of good quality was obtained locally and had the following analysis: CaO, 53.7 pct; MgO, 0.8; ignition loss, 42.4; R₂O₃, 0.2; SiO₂, 3.0; and P₂O₅, 0.014.

Melting Procedure

Sponge iron was melted to produce metal stock for the experimental alloys in a silica-lined, three-phase, direct-arc, size ST, Moore Rapid Lectromelt

Fig. 1—Electric arc furnace installation.

furnace with a 500 kva rating. Fig. 1 shows this furnace installation. About 25 tons of sponge iron was melted in 75 heats, averaging 927 lb of sponge iron to the heat. An addition of carbon was required to complete the reduction of a portion of the iron oxide remaining in the sponge to prevent high losses of iron oxide in the slag and a low carbon content in the resulting metal. As reducing agents in preparing the melting stock, charcoal, coke, and a carbon product resulting from the thermal decomposition of natural gas were used. The quantity varied from 20 to 60 lb per furnace charge, with an average of 38 lb. An average analysis of the metal obtained gave 0.52 pct C, about 0.01 pct Mn, 0.070 pct P, and 0.092 pct S. The average yield of metal was 647 lb with 241 lb of slag, the sponge-iron recovery being 70 pct. The metal obtained in melting the sponge iron was cast into pigs weighing about 20 lb each to facilitate recharging into the furnace for further refining. The pouring of the pigs is shown in Fig. 2. The average power consumption for the production of the 24 tons of metal obtained was 1704 kw-hr per ton.

Fig. 2—Pouring of pigs from lip pouring ladle.

No slag-making or alloy additions were made to these heats, as the metal was subsequently remelted to remove manganese, silicon, phosphorus, and sulphur in a basic-lined furnace under a high-lime oxidizing slag.

A series of 22 heats was made on the melting stock in the basic-lined furnace under the oxidizing slag. After the metal had melted, the oxidizing slag was removed and a reducing slag formed for additional sulphur removal. Considerable sulphur is removed from high-sulphur metal under an oxidizing slag, but the reducing slag removed it much more rapidly.

The results obtained in these 22 heats on the removal of phosphorus are clearly observed in Table I. Temperature control in the furnace had considerable influence on sulphur and phosphorus. High temperatures were necessary to obtain the reductions de-

sired. Where the melt-down carbon is very low, removal of phosphorus is excellent, but where melt-down carbon is high, phosphorus removal is very poor, indicating the oxidizing conditions necessary for good phosphorus removal. This table also shows the phosphorus pick-up in the metal during the reducing-slag treatment. Even though great care was taken in removing the oxidizing slag as completely as possible, some reversion of phosphorus took place during the reducing-slag treatment. After every other possibility was eliminated, it was concluded that the pick-up was obtained from the fireclay roof. It may be noted that a considerably larger pick-up than normal occurred in heat 26B. The reducing slag in this heat was held on the metal much longer than normal. The average increase in phosphorus during the reducing-slag treatment was 0.017 pct. During the latter part of the experimental work a virtually phosphorus-free basic roof was installed, and this phosphorus pick-up was eliminated.

The average sulphur removed by the oxidizing slag was 0.017 pct, whereas 0.067 pct was removed by the reducing slag.

These 22 heats were remelted under an oxidizing slag to remove further manganese, silicon, phosphorus, and sulphur. The results of the remelting are shown in Table II.

Heats 44, 47, and 48 did not receive further treatment. Heat 44 was tapped from the furnace and a 200-lb ingot with a hot top poured. The metal was killed by the addition of aluminum pellets. Carbon was added to the molten-metal bath of heat 47 to produce a material containing 3.72 pct C. Pigs from heat 47 were added to heat 48 to raise the carbon content to 0.20 pct. No reducing slag was used on these three heats. Table III shows the results of remelting the heats shown in Table II to produce the alloys used in the tests described in this paper. Heat 17 was remelted to produce heat 18, which in turn was remelted to produce heat 19. Heat 46 had no aluminum added for deoxidation. Heat 64 was remelted for phosphorus removal to produce heat 65 having a sulphur content of 0.002 pct.

Fabrication of Samples

One ingot with a hot top was poured from each final heat shown in Table III. The ingots weighed 200 to 220 lb and were 6x6x24 in. in length including

the hot top. These hot tops were cropped by sawing. The cropped portion of the ingot weighed about 50 lb, leaving about 150 lb to be worked into test specimens. The ingots were heated in a butane-gas-fired furnace to about 2300°F and forged under an air hammer to approximately 1-in. rounds. The rods were then cold-swaged in a rotary swager to 5/8-in. rods, samples being removed at 3/4-in. diam for tensile and other physical tests. The rods were annealed at intervals during the swaging to relieve the hardening induced by the cold-working operation.

Evaluation of Hot-Working Characteristics

The "hot-twist test" was selected as the most suitable means of conducting the elevated temperature tests in the hot short range. This method has recently been described by Clark and Russ¹ and Ihrig.² While not entirely satisfactory, the test yields reproducible results that serve as an indication of the hot-working properties of the metal. The equipment used is rather simple; and, as Clark and Russ pointed out in their studies, the test requires very little time and is a torsion test in which the predominating stresses are in shear.

Fig. 3 shows the equipment used for the test. It consists of a furnace for heating and maintaining

the specimen at the desired temperatures. The furnace has upper and lower sections which are hinged to allow easy placement and removal of the bar being twisted, and also to facilitate chucking the test pieces. A 3-hp motor with a reduction gear is attached to a chuck for holding and rotating the specimen. At the opposite end of the chuck end of the furnace the sample is held firmly by a dog, which prevents the specimen from rotating. All results except as otherwise noted were carried out at about 200 rpm and at 50° temperature intervals from 1550° to 2000°F. The temperatures used covered the red short range. By means of an electrical circuit, an automatic counter records the number of turns before failure. Table IV gives the analysis for carbon, manganese, silicon, phosphorus, and sulphur of the rods used in the experiments.

Table V shows the results of the twisting tests obtained on the rods containing varying amounts of sulphur. These results clearly show that, as the sulphur content of the metal decreases, the number of twists to failure increases. Heat 65, having only 0.002 pct S, shows very good hot-working properties. Hot-working properties of materials above 0.010 pct S are uniformly poor. Of two ingots containing 0.017 pct S, only one could be forged to produce rod for testing.

Fig. 4 shows the results of an attempt to forge an ingot from heat 55 containing 0.021 pct S. A few blows by the forging hammer fractured the ingot.

In all samples tested, a minimum number of twists was obtained in the hot-short range from about 1725° to 1825°F.

To determine whether the size of the rod influenced the results obtained in the test, rods of heat 19 were swaged to 5/8, 9/16, 7/16, and 3/8 in. in diam. The number of twists to failure for the rods of the various diameters is shown in Table VI. While these results indicate that the size of rod does not greatly influence the number of twists to failure, it is significant to note that, as the diameter of the rod decreases, the number of twists before failure increases.

To determine whether rate of twisting influenced the results of the twisting tests, a four-speed transmission was connected to the chuck used for twisting the rods. Rates of 47, 96, 180, and 290 rpm were obtained with this arrangement. Rods used were swaged to 3/8-in. diam for this series of tests. The results obtained are shown in Table VII. These re-

sults indicate that, as the rate of twisting increases, the number of twists to failure also increases.

Physical Testing

During the working-down schedule of the rods, samples for physical testing and metallographic examination were removed when the rods reached 3/4 in. in diam. The specimens were cut to length for heat treating. The samples were heat-treated and measured or examined in the normalized and annealed conditions. The normalized samples were heated to such a temperature that the material was in the austenitic range, held at that temperature for 1 hr, removed from the furnace, and allowed to cool

in still air. The annealed samples were given this same treatment but in addition were returned to the furnace after cooling, held for 30 min, the furnace heat turned off, and the specimens allowed to cool in the furnace. Duplicates were prepared on all samples.

Impact specimens were standard Charpy keyhole notch-type, with a breaking section of 0.197x0.394 in. Specimens were broken in a Tinius Olsen impact testing machine of 264 ft-lb capacity with a striking velocity of 16.5 ft per sec.

Rockwell-hardness measurements were made on all samples.

The Charpy impact values and the Rockwell B hardness of the samples are given in Table VIII.

Tensile specimens were tested by standard methods, using a threaded 0.505-in. diam test bar in a Baldwin-Southwark testing machine. The yield point was determined by the drop of the beam. The proportional limit and yield strength values were determined from stress-strain diagrams drawn by a Templin recorder.

The mechanical properties of the samples in the annealed condition are given in Table IX, while the results obtained on the normalized specimens are given in Table X. From the results of the various physical properties of the Fe-C-S alloys, it appears that the carbon content exerts the principal influence on these properties. All samples were exam-

ined under the metallographic microscope. The annealed samples in all cases contained larger grains and more, coarse lamellar pearlite than the normalized specimens. Fig. 5 shows a micrograph of Heat 50 in the normalized condition, while Fig. 6 shows the same alloy in the annealed state.

Summary

A series of Fe-C alloys has been prepared at the Redding, Calif., Station of the Federal Bureau of Mines in which the manganese is 0.004 pct or less with low phosphorus and silicon contents but with varying percentages of sulphur. The experimental alloys have been hot-forged and swaged to rods. Hot-twisting tests have been conducted on 5/8-in. rods. The physical properties of the alloys have been determined. Manganese-free Fe-C alloys with more than 0.017 pct S could not be hot-forged. Alloys with more than 0.010 pct S possess very poor hot-working properties. As the sulphur content of the alloys decreases below 0.009 pct, the hot-working properties of the alloys improve. Alloys containing 0.002 pct S exhibit excellent hot-working properties.

Acknowledgments

Acknowledgment is made to John L. Morning, Dean R. Myers, Edward Knakal, and A. G. Pike, former employees, who assisted in the work; to R. G. Dutton, who constructed the hot-twisting equipment and prepared most of the samples for the physical tests; and to E. D. White, who worked on the electrical equipment and conducted a number of hot-twisting experiments.

Stabilization of the Austenite-Martensite Reaction In a High Chromium Steel

by S. C. Das Gupta and B. S. Lement

No appreciable stabilization of the austenite-martensite reaction occurs in a 15 pct Cr-0.7 pct C steel unless some martensite is initially present. Stabilization is induced by interrupting the subcool below M_s ; however, disappearance of the stabilization effect as manifest by burst formation of martensite may occur on continued holding at the final sub-zero reaction temperature. The higher the temperature of intermediate cycling after the initial subcool, the more permanent is the stabilization effect at the final reaction temperature. Appreciable conditioning of retained austenite occurs on reheating to about 500°C. These phenomena are explainable on the basis of the reaction-path theory.

A RECENT investigation¹ carried out by the authors has shown that isothermal transformation of austenite to martensite definitely takes place in a 15 pct Cr-0.7 pct C steel and that appreciable amounts of martensite can form in this fashion. Investigations²⁻⁶ carried out on other steels and iron alloys make it seem probable that isothermal formation of martensite is a phenomenon of fairly general occurrence. The reaction-path theory of Cohen, Machlin, and Paranjpe^{5, 7} explains isothermal transformation on the basis of thermal activation of strain embryos which generate martensite plates with a velocity approaching that of sound. On the other hand, the nucleation and growth theory of Fisher, Hollomon, and Turnbull⁸ regards isothermal transformation as due to growth of athermally formed martensite nuclei. The experimental evidence obtained thus far favors the reaction-path theory in that the martensite reaction seems to be nucleation-controlled rather than growth-controlled.

Stabilization is another phenomenon of importance with respect to the austenite-martensite reaction. According to the reaction-path theory, stabilization is a result of relaxation of strain embryos. It is postulated that strain embryos are

present at the austenitizing temperature in the form of dislocations or lattice imperfections in the austenite which vary in the extent to which the lattice is displaced along the strain reaction path leading to martensite. On quenching from the austenitizing temperature, athermal martensite starts to form as soon as the M_s is reached, because the activation energy of the transformation which decreases with decreasing temperature is lowered to below the level of the highest energy strain embryos. Martensite plates are generated during the cooling below M_s from embryos possessing energies above the activation energy corresponding to the temperature at which the cooling is stopped. The distribution of lower energy embryos is changed because of the elastic and plastic strains produced in the remaining austenite as a result of the transformation. This effectively increases the number of strain embryos at all levels of energy below the activation energy and tends to stimulate further martensite formation either isothermally or on subsequent cooling. However, if the temperature at which the cooling is stopped is high enough for relaxation of strain embryos to occur, some degree of stabilization against further transformation may be induced. Whether stabilization will be observed on subsequent cooling will depend on the extent of decrease of activation energy with temperature. If the activation energy decreases sharply with temperature, it is possible that transformation will appear to continue with decrease in temperature in spite of the loss of embryos by relaxation. However, with a more gradual decrease in activation energy, stabilization will be manifest by no further transformation on cooling over a measurable temperature range until the

activation energy is decreased below the level of the highest energy embryos that survived relaxation.

Two mechanisms by which relaxation of strain embryos can occur have been proposed by the authors of the reaction-path theory. Relaxation could occur by a recovery process similar to that which occurs prior to recrystallization of cold-worked metals. Another possibility is diffusion of solute atoms such as carbon into strain embryo regions, which results in an increase in the activation energy associated with such regions because of increase in carbon content.

The present investigation was carried out in order to learn more about the characteristics of the austenite-martensite reaction in the 15 pct Cr-0.7 pct C steel. Experiments were designed primarily to study various aspects of stabilization; however, other effects were encountered. These experiments involved prior treatments such as reheating quenched specimens before cooling below M_s , interrupting the cooling below M_s , and cycling from temperatures below M_s to above M_s . The effects of these prior treatments on subsequent athermal and isothermal martensite formation at relatively low subzero temperatures were investigated as further tests of the adequacy of the reaction-path theory.

Experimental Details

The chemical composition of the steel investigated is as follows: C, 0.73 pct; Mn, 0.28; Si, 0.20; S, 0.02; and Cr, 14.84. Specimens approximately $1/16 \times 1/8 \times 1/4$ in. were sealed in an evacuated quartz tube and then austenitized for 2 hr at 1275°C which resulted in a grain size of ASTM No. 1 to 2 and virtually complete carbide solution. The M_s corresponding to this treatment was found to be $-65^\circ \pm 5^\circ\text{C}$. Quenching was carried out in a 10 pct brine solution maintained at 5°C . The quartz tube was broken under the surface of the quenching liquid. The details of the subzero furnace used to attain temperatures down to -150°C have been given previously.¹ Liquid nitrogen was used to attain -197°C . Quantitative determination of the extent of martensite formation was carried out by the method of lineal analysis.⁹ The precision measurement is estimated to be ± 1 pct martensite.

The common starting point for most of the experiments in this investigation was the as-quenched state of specimens quenched from 1275° to 5°C . The

specimens were completely austenitic at 5°C . Comparisons were made of isothermal transformation at temperatures of -130° to -197°C with and without prior treatments. The amount of martensite formed as a result of cooling directly to these temperatures was found to be higher than previously reported;¹ however, there was no measurable change in M_s temperature. This could be due to either a slight variation in chemical composition of the bar stock used or some undetermined variable in heat treatment. In order to make the comparisons more reliable, specimens were taken from approximately the same locality in the bar stock. Furthermore, these specimens were austenitized and quenched at the same time before being subjected to the comparative treatments of each experiment. For each experiment, the basis of comparison is treatment A, which consisted of subcooling specimens from 5°C to a subzero temperature, holding for a definite length of time, and upquenching to 20°C in water.

Results

Effect of Interrupting Cooling Prior to Subcooling below M_s : The M_s temperature, -65°C , as well as the amounts of martensite formed on cooling to subzero temperatures, was found not to be affected to any appreciable extent by holding specimens quenched from 1275°C even as long as 500 hr at 20°C prior to subzero cooling. These results seemed to be at variance with the findings of Klier and Troiano¹⁰ who concluded that stabilization occurs in this steel as a result of holding above M_s prior to cooling below this temperature. However, there was still the possibility that the stabilization process at 20°C is completed so rapidly that detection is difficult. Further experiments were carried out in order to check this point by duplicating Klier and Troiano's procedure in detail. Specimens $1/32 \times 1/32 \times 1/2$ in. were austenitized for 5 hr at 1200°C in purified nitrogen atmosphere. Quenching the specimens directly into refrigerated mercury from 1200°C resulted in an M_s of about $-35^\circ \pm 5^\circ\text{C}$. However, interrupting the quench from 1200°C for 1 hr at 20°C followed by subcooling also gave the same M_s ; thus, no stabilization effect was found. Microscopic examination of specimens austenitized at 1200°C revealed an appreciable amount of undissolved carbides, which means that both the carbon and alloy content of the austenite were lower than for the case of virtually complete solution obtained at 1275°C . This would account for the higher M_s (-35°C as compared to -65°C) resulting from the 1200°C treatment.

Effect of Reheating Prior to Cooling below M_s : In these experiments, specimens were reheated to temperatures as high as 500°C after quenching from 1275°C in brine at 5°C . These specimens were air cooled to room temperature and subsequently subcooled to -197°C . The amounts of martensite formed after holding zero and 30 min at this temperature were then measured. The effect of not reheating (treatment A) is compared with that of reheating to 250° and 500°C (treatment B) in Fig. 1.

It was found that reheating as high as 500°C does not have any appreciable effect on subsequent isothermal transformation at subzero temperatures. Likewise, reheating to below 250°C does not appreciably affect the amount of athermal martensite formed; however, a 500°C reheat does result in an increase in the amount of transformation formed on subsequent cooling to -197°C . It is possible that the increased athermal transformation is due to some

Fig. 2—Effect of cycling temperature on subsequent isothermal transformation at -150°C .

type of conditioning process that occurs in the retained austenite. This conditioning was not found to result in any noticeable increase in the M_s temperature; however, it is possible that a change less than 5°C would not have been detected with the metallographic method employed.

Effect of Cycling from below M_s : The effect of cycling between subzero temperatures below M_s to temperatures as high as 60°C on subsequent isothermal transformation was studied. The results of treatment C shown in Fig. 2 for a subzero temperature of -150°C and a 30 min hold indicate that virtually complete stabilization against isothermal transformation is obtained provided that a cycling temperature of 20°C or above is employed. Similar results were obtained for isothermal transformation at -197°C again using a 30 min hold.

This stabilization effect with respect to isothermal transformation was also found to depend on time at the cycling temperature. Using shorter times than 1 hr at 20°C was found to decrease the extent of stabilization at both -150° and -197°C .

Curiously enough, the stabilizing effect which is noticeable for comparatively short holding times at the final reaction temperature is somehow overcome

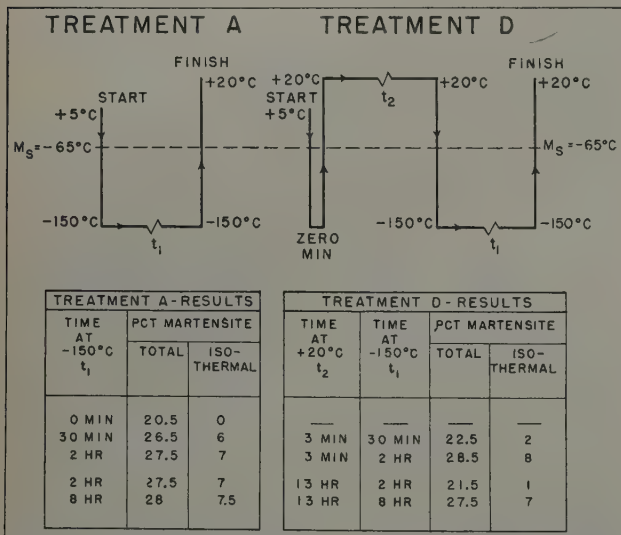

Fig. 3—Effect of time of hold at -150°C on extent of isothermal transformation following cycling treatment.

if longer times are employed. This phenomenon is shown in Fig. 3 for isothermal transformation at -150°C (treatment D). For example, the stabilization effect observed on holding 30 min at -150°C after cycling at 20°C , 3 min hold, appears to be completely overcome on continued holding for a total of 2 hr at -150°C . Similarly, after cycling at 20°C , 13 hr hold, the stabilization effect found on holding 2 hr at 150°C seems to disappear on continued holding for a total of 8 hr at this temperature. Further experiments at both -150° and -197°C established that the stabilizing effect tends to become more permanent the higher the cycling temperature or the longer the time at a given cycling temperature. For example, following 1 hr at 60°C , complete stabilization was found even after holding 6 hr at -150°C .

Effect of Interrupting Subcooling below M_s : In order to determine the effect of interrupted subcooling, specimens were first cooled to intermediate subzero temperatures in the range of -70° to -80°C , held to produce various initial amounts of martensite, and then further cooled to and held at lower subzero temperatures. The results of this procedure (treatment E) are given in Fig. 4.

As shown in Fig. 4, the total amount of martensite formed by treatment E which involved interrupted subcooling to and isothermal holding at either -130°

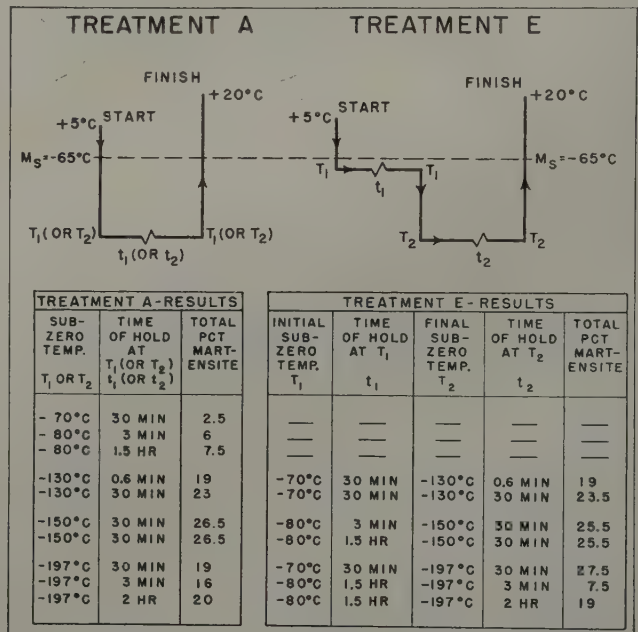

Fig. 4—Effect of interrupting subcooling below M_s on total transformation following holding at -130° , -150° , and -197°C .

or 150°C , is approximately equal to that formed by treatment A which involved direct subcooling to and isothermal holding at these temperatures. Apparently, the initial amount of martensite such as was formed at -70° or -80°C does not affect the total amount of transformation obtained on cooling to and holding at -130° or -150°C .

On the other hand, the situation is different if a final subcool to -197°C is used. The formation of about 2.5 pct martensite by an interrupted subcooling at -70°C for 30 min actually results in a greater total amount of martensite after subsequent cooling to and holding at -197°C for 30 min (treatment E) than after direct cooling to and holding at this temperature for the same time (treatment A). It would seem that the formation of a small amount of mar-

tensite by interrupted cooling has a stimulating effect on subsequent transformation on cooling to -197°C . However, if the amount of initial martensite is increased to about 7.5 pct by first cooling to -80°C and holding for 1.5 hr, essentially no further transformation takes place on subsequent cooling to and holding 3 min at -197°C . This indicates that the formation of a sufficiently large quantity of initial martensite can result in stabilization against further transformation on subsequent cooling to -197°C . However, if the time of holding at -197°C is increased from 3 min to 2 hr, the stabilizing effect of interrupted subcooling is overcome and approximately as much total martensite results as in the case of direct cooling to -197°C and holding for 2 hr. This is the same phenomenon that was observed as a result of treatment D, Fig. 3.

In order to study in more detail the stimulating effect associated with initial amounts of martensite, additional experiments were carried out. Specimens were subcooled to -70°C , held for 3 min to produce about 1 pct martensite, and finally cooled to -197°C . It was found that no further martensite formation occurred during the cooling to -197°C . However, on holding at -197°C for only 3 min about 14 pct martensite formed. This indicates that the stimulating effect is a complex phenomenon, first inducing stabilization against subsequent transformation on cooling from -70° to -197°C and then facilitating the formation of a relatively large amount of martensite on holding at -197°C for only a short time.

Microexamination of the specimens used in these experiments revealed that the small amount of martensite that formed during the initial subcool was mainly concentrated in the vicinity of the center of the specimen and was normal in appearance. On the other hand, the much larger amount of martensite that formed on holding at -197°C was found situated mainly in the region between the center zone and surface of the specimen. Furthermore this outer zone of martensite was found to possess a marked "zig-zag" appearance. It is believed that this type of martensite formation is due to the burst phenomenon reported by Machlin and Cohen¹¹ and Kulin.¹² The burst type of martensite formation was observed in all cases of stimulation associated with small initial amounts of martensite in the present

investigation. Micrographs in Fig. 5 show the difference between normal formation and burst formation of martensite.

The normal formation shown in Fig. 5a, which resulted from direct subcooling to and holding at -197°C , is typical of the entire specimen area except for occasional "zig-zag" martensite configurations which occur to a minor extent. The burst formation shown in Fig. 5b, which resulted from interrupted subcooling followed by cycling prior to the final subcool to and hold at -197°C , is typical of the major portion of the specimen area except for a small region at the center which possesses a normal appearance. The effect of cycling following interrupted subcooling is discussed in more detail in the next section.

Effect of Cycling Following Interrupting Subcooling below M_s : In these experiments, specimens were cooled to a subzero temperature such as -80° or -90°C to form some martensite initially, reheated

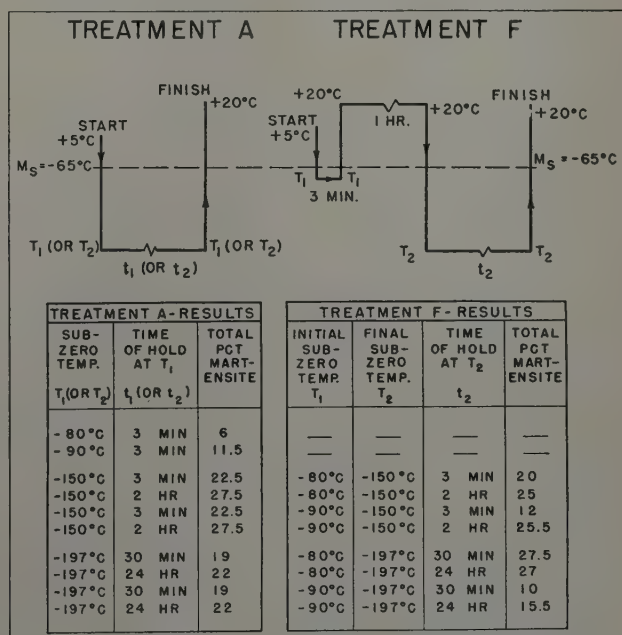

Fig. 6—Effect of cycling at 20°C following interrupting subcooling below M_s on total transformation after isothermal hold at -150° and -197°C .

Fig. 7—Variation of amount of martensite formed by final subcool to -197°C with initial amount present and reheating temperature employed.

to 20°C , and finally cooled to -150° or -197°C . In Fig. 6 the effect of this cycling (treatment F) on total amount of martensite formed is compared with that of direct subcooling to and holding at the same final temperature (treatment A). Starting with 6 pct martensite (3 min at -80°C), cycling up to 20°C and back to -150°C results in a slightly lower amount of martensite as compared with treatment A. However, if the final subzero temperature is -197°C , a significant increase in total amount of martensite occurs. This indicates that it is possible to start with the same amount of martensite and incur either stabilization or stimulation depending on whether the final reaction temperature used is -150° or -197°C .

Variation of Critical Amount of Martensite with Reheating Temperature: Experiments were carried out to determine how the amount of initial martensite that is critical with respect to obtaining stimulation or stabilization is affected by reheating temperature. The procedure used is similar to treatment F except that reheating temperatures of 250° and 500°C as well as 20°C were employed. When reheating was carried out at temperatures of 250° and 500°C , the initial martensite was tempered but no transformation of the retained austenite took place. The tempering of the initial martensite provided a means of distinguishing in the same specimen between initial martensite and martensite formed on subcooling following the reheating treatment. The final subzero temperature used was -197°C and specimens were held 30 min at this temperature. The variation in the amount of initial martensite was produced by the initial treatments shown in Table I.

The results of reheating are shown in Fig. 7, which is a plot of amount of martensite formed subsequent to the initial treatment as a function of the amount of martensite initially present. These results confirm that for each temperature of reheating there is a critical limit of initial amount of martensite above which complete stabilization is induced against further transformation on subsequent subcooling to -197°C . For initial amounts of martensite below

these limits, stimulation of the austenite apparently occurs and even more total martensite forms than for the case of zero initial martensite. These limits and the possible experimental errors are 7.5 ± 1.5 pct, 2.5 ± 1 pct, and 13 ± 1 pct for reheating temperatures of 20° , 250° , and 500°C , respectively. Thus it appears that the critical limit first decreases with increase in reheating temperature from 20° to 250°C and then increases again somewhere in the range of 250° to 500°C .

It was shown in Fig. 1 that by reheating to 500°C without any initial martensite present, there results an increase in the subsequent transformation on cooling to -197°C and this was attributed to the phenomenon of conditioning. It is also believed that the marked increase in critical amount of martensite required for complete stabilization using a reheating temperature of 500°C as compared to 250°C , as shown in Fig. 7, is also due to conditioning. This would mean that two opposing effects, stabilization and conditioning, occur as a result of reheating above about 250°C .

Discussion of Results

Relation of Partial Transformation to Stabilization: Whether partial transformation must occur before austenite can be stabilized against further transformation on cooling is still open to question. Although Harris and Cohen¹³ and Machlin and Cohen⁶ report that stabilization occurs only if the cooling is interrupted below M_s , Klier and Troiano¹⁰ and DeLazaro et al.¹⁴ report that stabilization can be induced if the cooling is interrupted above the M_s , determined by continuous cooling. Attempts made in the present investigation to duplicate in detail the experiments of Klier and Troiano¹⁰ on the same heat of 15 pct Cr-0.7 pct C steel failed to give the same results.

The reaction-path theory does not preclude the occurrence of stabilization as a result of interrupting the quench from the austenitizing temperature prior to cooling below M_s . If it is assumed that the distribution of strain embryos existing at the austenitizing temperature is retained on quenching to a temperature above M_s , relaxation of such embryos would not be expected to occur by the process of recovery. After all, these embryos survived exposure to the austenitizing temperature where recovery would be much more potent. It is possible, however, that relaxation could occur by diffusing of carbon atoms into strain embryo regions. At the high austenitizing temperature, the tendency for such clustering of carbon atoms would be opposed by the increased entropy associated with a random carbon distribution. After quenching to above M_s , the entropy effect would be reduced, and an overall decrease in free energy could result if carbon atoms diffuse into strain embryos. Such regions offer a greater amount of interstitial space than the more perfect regions of the lattice and a decrease in distortional energy would be expected. In order to account for the failure to observe stabilization in the present investigation as a result of interrupting the quench at room temperature or reheating the as-quenched austenite to as high as 250°C , it seems necessary to assume that the rate of diffusion of carbon in the austenite of the 15 pct Cr-0.7 pct C steel is too slow to have any appreciable effect in the temperature range studied.

On the other hand, stabilization was found to take place as a result of heating in the same temperature range provided that partial transformation of austenite to martensite had previously occurred. On the

Table I. Amount of Martensite Formed by Initial Subcooling Treatment

Initial Treatment	Range of Pct Martensite Formed
Cooled to -70°C and held for 3 min	Trace to 1
Cooled to -70°C and held for 30 min	1 to 3
Cooled to -80°C and held for 0 min	2 to 4
Cooled to -80°C and held for 3 min	4 to 7
Cooled to -90°C and held for 0.6 min	5 to 8
Cooled to -90°C and held for 3 min	10 to 13
Cooled to -100°C and held for 3 min	12 to 14

basis that diffusion of carbon atoms into strain embryos results in relaxation, this would mean that for some reason the rate of diffusion of carbon in austenite is increased when some martensite is present. According to the reaction-path theory, generation of martensite plates results in the simultaneous formation of new strain embryos in the vicinity of these plates where both elastic and plastic deformation of the remaining austenite has occurred. Since the activity of carbon in martensite is presumably higher than in austenite even of the same composition, there would be a pronounced tendency for carbon atoms to diffuse from the edges of the martensite plates into strain embryos in the adjoining austenite.

Partial transformation appears to be a prerequisite for stabilization against both athermal and isothermal transformation of austenite to martensite. Stabilization against isothermal transformation was induced by first cooling to a subzero temperature below M_s and then cycling to 20°C or above before returning to the same subzero temperature for observance of isothermal transformation. It was found that the degree of stabilization increases with increase in both cycling temperature and time at a given cycling temperature. This would be expected on the basis that relaxation of strain embryos whether due to recovery or diffusion of carbon would be greater the higher the temperature or the longer the time.

Burst Formation: It has been shown that with small initial amounts of martensite formed by interrupting the subcool below M_s , it is possible to end up with more total martensite after subsequent cooling to and holding at -197°C than by direct subcooling to and holding at -197°C for the same length of time. This stimulating effect associated with small amounts of initial martensite is attributed to stabilization against transformation on subsequent cooling to -197°C followed by burst formation at this temperature. Stabilization as induced by interrupted cooling below M_s may be due to a decrease of high energy strain embryos resulting from both relaxation and isothermal transformation. In view of the small amount of isothermal transformation involved, it seems likely that relaxation plays the major role in inducing stabilization.

The burst phenomenon has been described by Machlin and Cohen.¹³ The activation of a sufficient number of strain embryos simultaneously either during cooling or at constant temperature is believed to create sufficient momentum to start a chain reaction. This results in a relatively large increment of transformation occurring practically instantaneously. The temperature at which this phenomenon first occurs on cooling is called the martensite burst point and is designated as M_b . It is apparently necessary to cool the austenite of the 15 pct Cr-0.7 pct C steel to approximately -197°C in order to lower the activation energy sufficiently to facilitate burst formation of martensite.

In the present investigation it was found that the tendency for burst formation is markedly inhibited if the initial martensite content exceeds a critical amount. Interrupting the subcool below M_s results in initial formation of martensite in the region of the center of the specimen. This location is to be expected since the specimen in the as-quenched condition has a residual stress distribution varying from compression at the outside to tension at the center, and Kulin¹² has shown that martensite for-

mation is aided by residual tension and hindered by residual compression. With increase in the amount of martensite that is allowed to form as a result of the initial subcool, the zone of transformation which has a normal appearance spreads out from the center of the specimen. When the specimen is subsequently cooled to -197°C, it is observed that burst formation is restricted to the remaining rim of untransformed austenite. By allowing the formation of sufficient initial martensite, it is possible to virtually eliminate the untransformed rim and thereby suppress burst formation of any appreciable magnitude on subsequent cooling to and holding at -197°C.

That burst formation is mainly restricted to the rim of untransformed austenite is probably due to the constraints resulting from subdivision of austenite by the martensite plates formed initially at the center zone of the specimen. The degree of cooperation required for burst formation is probably lowered by the obstructing action of martensite plates with respect to the propagation of strain associated with a burst. These plates probably act as the walls of partial enclosures in which triaxial compressive stresses are set up when a transformation strain is encountered. Kulin¹² has shown that such a stress condition externally applied to the specimen as a whole can result in a lowering of both M_s and M_b .

It was found that the critical amount of initial martensite required for complete suppression of burst formation over a period of 30 min at -197°C decreases as a result of intermediate cycling to increasing temperatures up to about 250°C. By cycling to 250°C, the critical limit was reduced to about 2.5 pct, which is not a sufficient amount to allow the central zone of normal martensite to encompass the entire volume of the specimen. In this case, the failure to observe the occurrence of burst formation in the untransformed rim may be due to the high degree of relaxation resulting from heating to 250°C. Sufficient relaxation of strain embryos situated at the outside fringes of the center zone of normal martensite formation might prevent them from triggering off bursts on subsequent cooling to and holding at -197°C.

Disappearance of Stabilization: As has been previously discussed, stabilization induced by interrupting the subcool below M_s is more pronounced the greater the initial amount of martensite formed prior to cooling to and holding at the final subzero reaction temperature. With small amounts of initial martensite, stabilization is apparently overcome in very short periods of time at -197°C by burst formations of relatively large magnitude which occur discontinuously. With larger amounts of initial martensite exceeding what is called the critical limit, stabilization seems to be more permanent. However, after sufficient time at the final reaction temperature, the stabilization effect tends to disappear. Disappearance of stabilization is manifest by isothermal formation of martensite starting after what may be either an incubation period or else a period during which the rate of transformation is too slow to be detected with the metallographic method employed. If the holding time at the final reaction temperature is sufficiently long, the original handicap in martensite content can apparently be overcome and about the same total amount of transformation results as formed by direct cooling to and holding at the same reaction temperature for the same period of time. However, the higher the cycling temperature used prior to cooling to the final

reaction temperature, the more permanent is the stabilizing effect.

In the previous investigation the authors found that the rate of isothermal transformation is maximum at the start and then decreases with time. According to the reaction-path theory, the initial rate of isothermal transformation is maximum because at zero time the distribution of strain embryos is most favorable; with increase in time the higher energy embryos are used up in generating martensite and the rate decreases.

Apparently the situation is different with respect to isothermal transformation following stabilization since the initial rate is definitely not maximum and may even be zero. The results of microexamination of specimens in which disappearance of stabilization occurred indicate that this phenomenon may be due to both normal and burst formation of martensite. Machlin and Cohen¹¹ report the occurrence of a series of bursts either with or without periods of gradual transformation at constant temperature. Such a complex behavior is difficult to analyze.

Conditioning: On reheating to temperatures of above 250°C, the phenomenon of conditioning is encountered. This results in more martensite being formed at a subzero temperature than is the case for subcooling without an immediate reheating treatment. Conditioning appears to occur whether or not some martensite is initially present.

In the tempering of high speed steel, conditioning of the retained austenite results from precipitation of carbides which lowers the carbon and alloy content of the austenite and makes it susceptible to transformation to martensite on cooling from the tempering temperature to room temperature. No actual precipitation of carbides from austenite was observed microscopically as a result of heating the 15 pct Cr-0.7 pct C steel to temperatures as high as 500°C; however, it is believed that local changes in chemical composition on a microscopic scale do occur in preparation for formation of isothermal products such as bainite. These segregations within solid solution could yield low carbon regions which are more unstable with respect to transformation into martensite than high carbon regions. On cooling, the low carbon regions should facilitate martensite formation and thus yield a greater amount of transformation on reaching low subzero temperatures. Since both conditioning and stabilization tendencies become stronger the higher the temperature of reheating, the actual martensite formation on subsequent subcooling depends on the relative potency of the two opposing effects.

Summary

The results of this investigation of the austenite-martensite reaction in a 15 pct Cr-0.7 pct C steel are as follows:

1—No appreciable stabilization against athermal or isothermal transformation results unless partial transformation has occurred previously.

2—By interrupting the subcool below M_s and forming small amounts of martensite, stabilization is induced on subsequent cooling. If the final cooling is to -197°C , burst formation of martensite results on holding for very short times at this temperature.

3—When the amount of martensite as formed by interrupting the subcool below M_s exceeds a critical limit, the stabilization effect induced on subsequent

cooling to low subzero temperatures is more marked. However, disappearance of the stabilization effect eventually occurs on continued holding at such temperatures.

4—For a given amount of initial martensite, the higher the temperature of intermediate cycling the more permanent is the stabilization effect at the final subzero reaction temperature.

5—Appreciable conditioning of retained austenite results from reheating to about 500°C with or without the existence of prior transformation.

The reaction-path theory has proved extremely fruitful in providing general explanations for the above phenomena.

Effects of Macrostructure on the Performance Of Alnico Permanent Magnets

by Dolph G. Ebeling and Arthur A. Burr

The effects of casting texture, grain orientation and grain size upon the performance of Alnico permanent magnets is described. Single-crystal specimens were produced by special sintering and grain coarsening techniques to study the effect of crystal orientation. In addition to texture and orientation effects, an analysis of the results indicates that the permanent magnet performance is impaired by a refinement of the grain size.

AN excellent historical review of the development of Alnico permanent magnets has been prepared by Bozorth.¹ The desirable permanent magnet characteristics of Fe-Ni-Al alloys were discovered in 1932 by Mishima.^{2,3} The work of Ruder⁴ showed that the alloys were age-hardenable, and Betteridge⁵ defined the best composition and heat treatment for the magnetically isotropic alloy known as "Alnico 3." Horsburgh and Tetley⁶ increased the energy product by the addition of cobalt and copper, "Alnico 2," and Oliver and Sheddon⁷ demonstrated that cooling in a magnetic field improved the residual induction of this alloy. Jonas^{8,9} then disclosed the great practical benefits of heat treating an alloy of higher cobalt content in a magnetic field and the resulting alloy, "Alnico 5," has become the standard of the industry. This paper describes the fundamental aspects of a procedure which can be used to further improve the properties of these anisotropic permanent magnet alloys.

A study of the casting techniques used in the production of anisotropic Alnico permanent magnets

Discussion on this paper, TP 3433E, may be sent, 2 copies, to AIME by Dec. 1, 1953. Manuscript, April 16, 1952. Cleveland Meeting, October 1953.

This paper is based on a thesis by D. G. Ebeling submitted in partial fulfillment of requirements for a Doctor of Philosophy degree to the Department of Metallurgical Engineering of Rensselaer Polytechnic Institute.

indicated that the magnetic quality was affected by the as-cast macrostructure. Improved performance was observed in magnets containing a high percentage of columnar grains whose long axes were parallel to the magnetic axis of the casting. McCaig¹⁰ studied the effect of such columnar grain structures upon the magnetostriction characteristics of similar alloys, however no data was presented showing the effects on other magnetic properties. The following paragraphs describe two experiments which were conducted to determine the effect of various grain orientations upon the energy product.

Special composite molds were prepared of highly conductive and highly refractive components to remove the heat of solidification from the casting in a controlled manner. Representative macrostructures produced by these techniques are shown in Fig. 1, along with the relative volumes of favorably oriented columnar grains. The alloy, Alnico 5, has the highest permanent magnet performance of any commercial magnet material. It has the nominal weight composition of 8 pct Al, 14 pct Ni, 24 pct Co, 3 pct Cu, and 51 pct Fe. A heat of this material was cast into molds producing the type A and B grain structures shown in Fig. 1 and pairs of the resulting magnets were placed in heat-treating boats so as to eliminate any biasing effects of boat position. After a standard heat treatment the type A magnets, with 16 pct of the volume composed of favorably aligned grains, had a maximum energy value of 3,940,000 gauss-oersteds, while the type B magnets with 73 pct aligned grains averaged 5,090,000. This large im-

Fig. 1 — Macrostructures developed in directionally chilled, cylindrical castings of Alnico.

provement was obtained with a 57 pct increase in the volume of aligned grains, which indicated a difference of two million in the energy product between the fully aligned and fully unaligned macrostructures.

In another experiment, a portion of an 800 lb heat of Alnico 5 was cast into two types of molds so as to produce magnets of the types C and D shown in Fig. 1. A total of 236 pairs of these magnets were heat-treated in such a manner as to eliminate any spurious effects of loading. The results showed that the type C magnets with 36 pct of the volume composed of favorably aligned grains had a maximum energy value of 4,470,000, while the type D magnets with 68 pct aligned grains averaged 4,950,000. This 480,000 improvement in energy was realized with a 32 pct increase in the volume of aligned grains. This ratio extrapolates to a one and one-half million energy change between the two extreme types of macrostructure. Other experiments substantiated these indications of an important crystallographic factor affecting the quality of these permanent magnet alloys and after a study of the production aspects of the problem, a means of achieving controlled macrostructures was successfully reduced to practice.¹¹ Although the beneficial effects of certain grain structures had been demonstrated, it was of interest to establish an explanation for this behavior.

Theory

Two explanations were proposed for the previous observations. To facilitate a discussion of these proposals it is appropriate to review the magnetic characteristics that are important in the evaluation of permanent magnet materials. For this purpose, reference is made to Fig. 3.

B_r : The "ferric induction" is the peak induction, or B value, minus the peak magnetizing field, or H value.

B_c : The "residual induction" is the magnetic induction corresponding to zero magnetizing force after the material has been magnetized to saturation.

H_c : The "coercive force" is the magnetizing force required to bring the induction to zero after the material has been fully saturated.

BH_m : The "maximum energy" is the commonly accepted criterion of the excellence of a permanent magnet, and it is the product of B and H at the point in the demagnetization curve where this product is a maximum.

C : The "curvature ratio" is a dimensionless number which serves as a useful measure of the squareness of the hysteresis loop and it is defined by the

$$\text{relation: } C = \frac{BH_m}{B_r \cdot H_c}.$$

This relationship emphasizes the simple dependence of the magnet quality on three basic factors, namely: 1—The ferric induction which is controlled by the chemical composition; 2—the coercive force which is largely dependent upon the structures and lattice strains developed by the precipitation hardening reaction; and 3—the curvature ratio which will be shown to be related to crystallographic factors, such as grain orientation and grain size. In terms of these basic parameters the principal effect of the favorably oriented macrostructures was found to be an increase in the curvature factor, that is to say, to produce a square-shaped hysteresis loop. The proposed explanations of these columnar grain effects will now be presented.

In one hypothesis it was assumed there was a crystallographic "direction of easy magnetization" in these permanent magnet alloys. Single-crystal studies have shown that hysteresis curves measured in the direction of easy magnetization are rectangular in shape, whereas measurements in other crystallographic directions produce skewed hysteresis loops.¹²⁻¹⁴ The high curvature factors and energy values of these directionally chilled Alnico magnets could be explained if the crystallographic textures developed in these chilled castings corresponded to the direction of easy magnetization. There were good grounds for this supposition since all body-centered cubic metals solidify with [100] casting textures and this is just the direction of easy magnetization in soft magnetic alloys having a body-centered cubic structure.

The second explanation of the columnar grain effects was based upon different grounds. Aside from the postulated difference in texture, the macrostructures shown in Fig. 1 differ greatly in the number of grain boundaries intercepted by the magnetic axis. At each grain boundary, the stable direction of magnetization must change and, hence, the internal magnetic path must be discontinuous. In magnets composed largely of favorably aligned columnar grains there are fewer interruptions in the domain path than in an unfavorably aligned structure. Intuitively, it appears that the fewer the interruptions, the more stable will be the resulting domain configuration. This paper describes an investigation which was conducted to examine the validity of these proposed mechanisms.

Procedure

Single crystals were required to study this problem. The standard techniques for growing single crystals from the melt and in the solid state were applied to these alloys without success. Crystal growth from the melt had been found impractical due to the excessive loss of aluminum while holding these 8 pct Al alloys in the molten state for a period of time

sufficient to grow massive crystals. Grain growth in the solid state did not appear promising, since prolonged exposure to high temperatures resulted in only slight grain coarsening.

An investigation of the powder metallurgy technique was then conducted, since abnormal grain growth had been observed in a few samples of sintered Alnico 5. In the first experiment a heat of 50 pct Al-50 pct Co was prepared in a small induction furnace and subsequently reduced to -200 mesh powder. This powder was made into an Alnico 5 mix and pressed into $\frac{1}{2} \times \frac{1}{2} \times 3$ in. test bars. These bars were placed in sintering boats containing burnt alumina powder and mechanically pushed through a hydrogen atmosphere sintering furnace at such a rate that the bars were at a maximum temperature of 1380°C for 4.5 hr. These bars were fractured after sintering and all but one exhibited the normal, fine-grained macrostructure. As shown in Fig. 2 this remaining specimen contained a massive crystal surrounded by numerous cavities and a badly distorted, fine-grained surface layer. Microscopic examination revealed a fine, flocculent white powder on the surface of these voids which was taken to be alumina.

To minimize the formation of oxide films at the particle boundaries, an attempt was made to reduce the oxygen content of the powder compact. Two additional Al-Co heats were melted; in one the Al:Co ratio was 50:50 while in the other it was 25:75. These heats were ball-milled to -200 mesh under liquid toluene in which was dissolved a small amount of paraffin. The toluene was added to minimize oxidation during milling and the paraffin was expected to provide protection against oxidation during subsequent handling and pressing operations. Bars were prepared from these mixes and, after sintering, it was found that all the bars containing the 50:50 mix were fine-grained, porous, and distorted, whereas the 25:75 mix produced bars having smooth surfaces, practically no distortion, and massive crystals. There was still a thin layer of fine-grained material on all external surfaces which varied in thickness from 0.010 to 0.050 in. This performance was repeated a number of times and,

at one point, 48 out of 50 consecutive bars developed massive crystals.

Having achieved a successful method of producing large crystals, several subsidiary investigations were conducted. A study of the sintering times showed that the growth of the massive crystals occurred in only 30 pct of the bars if the time at temperature was reduced from 4.5 to 2.6 hr. Other experiments were conducted to eliminate the thin surface layer of fine-grained material. Surface treatments, protective shields, and the addition of "getters" to the burnt alumina were investigated and although getter powders were partially effective, this fine-grained skin was never completely eliminated. In all subsequent work this thin surface layer was removed by surface grinding.

The orientations of a large number of grains were determined by X-ray methods to learn if there were any possibility of controlling the orientation of the large crystals. It was found that no characteristic textures were developed about either the pressing or sintering directions. In view of these results, larger compacts were prepared and single-crystal

* Angles (a-b) in Fig. 4.

specimens of suitable size and orientation were obtained by cutting and grinding operations.

These larger bars measured about $\frac{3}{4} \times 1 \times 7$ in. Upon removing the fine-grained skin they were found to contain a number of large grains. The surfaces were polished and etched to delineate the grain boundaries and the orientations of the individual grains were determined by the Laue technique. All sides of each crystal were ground on a surface grinder to obtain the parallel faces which were necessary for accurate magnetic testing. These crystals fractured on the cube planes very readily and great care was required to avoid overheating or stressing during the cutting and grinding operations. The final specimens were not identical in shape but a representative size was $\frac{1}{4} \times \frac{3}{8} \times \frac{3}{4}$ in. Laue photograms were taken on each end of each specimen to determine the orientation of the magnetic axis and to detect the presence of any spurious grains.

These crystals had to be heat-treated in a magnetic field to develop their maximum magnetic properties. Above the Curie temperature the permeability of Alnico is roughly that of air and the magnetic lines of flux inside the directionalizing coil are essentially parallel. Upon cooling below this temperature the permeability of the Alnico increases sharply and this causes the lines of flux to be focused toward the higher permeability material. If not corrected, the divergent flux pattern created at the ends of the magnet would cause the material to be permanently directionalized in this manner with a resulting loss in performance. To combat this condition, Alnico pole pieces were placed at the ends of the magnets to concentrate the lines of flux and focus a parallel magnetic field on the magnet under treatment.

Each crystal with its carefully matched pairs of Alnico 5 pole pieces was aligned in a heat-treating boat, blocked in position with pieces of firebrick, and covered with sufficient burnt alumina to provide the proper cooling rate in the magnetic treatment. Unless otherwise noted, the heat treatment consisted of a 30 min, 1300°C solution treatment in a hydrogen atmosphere followed by a cooling treatment in a magnetic field of 1400 oersteds under

such conditions that the cooling rate in the region from 1100° to 800°C was about 100°C per min. These crystals were removed from the field when black and aged at 600°C for 6 hr. Finally, the crystals were demagnetized, polished, dimensioned, and prepared for test by carefully wrapping and cementing a "B" coil about the center cross section of the specimen. The magnetic tests were conducted in an electromagnet using a standard magnetizing field of 3000 oersteds.

Near the end of this program, it was found possible to grow large single crystals in two cast materials having compositions which differ from the straight Alnico 5 by the addition of minor amounts of titanium, silicon, and zirconium. The addition of a few percentages of titanium to Alnico 5 greatly increases the coercive force, and this high coercivity grade is commonly known as Alnico 6. The other

Table II. Sintered Alnico 5

C	0.54	0.66	0.67
$BH_m \times 10^{-3}$	4,200	5,900	6,000

modification of Alnico 5 is achieved by the addition of minor amounts of silicon and zirconium.¹⁵ These additions retard the precipitation hardening reaction to such an extent that overaging of the casting while cooling in the sand molds is prevented and therefore the 1300°C solution treatment is not required.

The production of large grains in castings of these modified compositions warrants comment, since this had not been possible in the case of the straight Alnico 5. In addition to their other specific effects, the titanium, zirconium, and silicon additions in these alloys tend to refine the as-cast grain size, presumably as a result of the nucleation effects of compounds formed by these elements. The resulting increase in the grain boundary area greatly increases the grain boundary energy responsible for grain growth, and it also reduces the concentration of impurities in these grain boundaries. This increase in grain boundary energy coupled with the decreased resistance to growth offered by the less contaminated boundaries is believed responsible for the formation of the massive crystals. This view of the abnormal grain growth experienced in these materials is supported by the behavior of the relatively fine-grained, sintered Alnico. In this case, the grain boundary area is extremely large and the impurity content of the boundaries is low because there is no segregation

of foreign atoms such as occurs during the selective solidification of a melt. The necessity for the extreme precautions against surface contamination of the powder particles may also be explained in terms of this impurity concept.

Results

The data obtained in this work is presented so as to show the correlation between the crystallographic orientation of the magnetic axis and the various magnetic properties. For this purpose, the orientation of the magnetic axes in these single crystals is represented by a point in the unit stereographic triangle. The coordinates of this point are given by a pair of angles (*a-b*), the first measured along a [100] zone from the [100] pole to the meridian of the magnetic axis, while the second angle is measured along this meridian between the magnetic axis and this [100] zone, Fig. 4.

Sintered Alnico 5 Crystals: One set of five crystals was cut from sintered bars made from the same mix; these pieces were heat-treated simultaneously and tested in the direction of the magnetic field during heat treatment with the results shown in Table I. These results show a large variation in the maximum energy value as the angle between the magnetic axis and the cube pole is increased. The 25 pct variation in the maximum energy can be attributed primarily to the change in the curvature factor, since the saturation values are unchanged and the coercivity is increased by only 8 pct.

Eighteen additional determinations were obtained on crystals of random orientations, and while the

Fig. 4—Unit stereographic triangle showing the coordinate system used to identify the orientation of the magnetic axis.

cipal crystallographic directions. These crystals were cut from adjacent grains of the same sintered bar so the chemical compositions and the pressing and sintering conditions were identical for all specimens. They were heat-treated simultaneously using six sets of carefully matched flux collectors. The results of the wet chemical analyses taken on pieces of these crystals and the magnetic data are summarized in Table III.

These data, particularly those obtained in tests 45, 49, and 50, demonstrate the marked dependence of the magnetic properties upon the crystallographic orientation of the magnetic axis.

Cast Alnico 6 Crystals: The fracture of a large Alnico 6 casting indicated that grain coarsening had occurred in one section of the piece during heat treatment at 1260°C. This casting was surface ground, polished, and etched to reveal several large grains from which suitable single-crystal specimens of the desired orientations were obtained. In addition, a similar shaped specimen was prepared from a fine-grained portion of the same casting. The chemical and magnetic results are given in Table IV.

The same orientation effects are found in this material as in the case of the sintered Alnico 5, however, the difference between the highest and lowest energy values is greater: 3,650,000 for Alnico 6 vs 2,250,000 gauss-oersteds, in the case of Alnico 5.

Cast Alnico 5 Crystals: In view of the previous results, an attempt was made to develop the ultimate properties of an Alnico permanent magnet. The Si-Zr modification of Alnico 5 was selected for this purpose because this material has a higher intrinsic magnetization than either the porous sintered Alnico 5 or the titanium-bearing Alnico 6. A large casting of this material was subjected to a grain coarsening treatment which consisted of 12 hr at 1300°C followed by 50 hr at 1200°C. This treatment produced large grains from which were obtained two single-crystal specimens. When the 900°C directionalizing treatment was applied to these specimens, the resulting energy product was very low, possibly as a

data confirmed the trend toward high values in the [100] region and low values near the [111] axis, there was some scatter in the results. This variation was due partly to the fact that the specimens did not come from the same mix and had not been sintered or heat-treated at the same time. There was an abnormal variation in the ferric induction values and this was traced to a significant variation in the density of the specimens. Microscopic examination revealed minute voids in these sintered single crystals and this porosity accounted for the variations in density which ranged between 94.4 and 98.7 pct of the theoretical value.

At this point in the program the crystal preparation techniques had improved, and it was possible to cut specimens with any desired orientation. The orientations of major interest were at the corners of the unit triangle and the next set of crystals afforded a comparison of a cube oriented specimen with one having nearly a [110] orientation. The detailed results are given in Table II and they demonstrate the appreciably greater curvature and maximum energy values associated with the cube orientation.

To amplify these results another set of six specimens was prepared which covered the three prin-

Table V. Cast Alnico 5

result of excessive precipitation during the 1200°C coarsening treatment. Consequently, the material was subjected to a 1300°C solution treatment which was followed by another 900°C directionalizing treatment and a 6 hr age at 600°C. The results obtained on the more favorably oriented crystal after these treatments are given in Table V.

Although this seven million energy value was about 50 pct greater than the normal values obtained on this material, an attempt was made to improve the performance still further. In the course of this and other investigations on Alnico magnets, it was found that very deleterious surface conditions could be developed on magnets by prolonged exposures to high temperatures. Microscopic examination of these layers showed that they were heavily precipitated and such a structure is known to produce a very low coercive force. The existence of such a surface layer appeared likely on this reheat-treated specimen, so 0.020 in. was ground off all sides of this crystal. The following results were obtained on this reground specimen: B_r , 14,250; B_r , 13,750; H_c , 690; C , 0.77; and BH_m , 7,590,000. The actual test results are presented in Fig. 5, which illustrates the extreme "squareness" of the demagnetization curve. The curvature ratio of 0.77 was the highest observed in this work, as was the energy value of 7,590,000 gauss-oersteds.

Cast Textures: A large cylindrical slab of Alnico 5 approximately 10 in. in diameter and 2 in. thick was cast using a metal chill on the bottom surface. A uniformly oriented, columnar grain structure was

produced in the center of this casting and the individual grains were of sufficient size to obtain Laue photograms. The orientations of the prominent grains in a sample cut from this structure were determined by James¹⁶ and the results are reproduced in Fig. 6 in the form of a distribution plot showing the orientation of the cooling direction in the various grains of this directionally chilled casting. The concentration of points near the cube pole, particularly those obtained on the ten longest columnar grains, demonstrates the existence of a cube texture in these directionally chilled castings.

Discussion

Crystal Orientation Effects: The results of the investigations on sintered Alnico 5 and cast Alnico 6 are summarized in Table VI.

These values conclusively demonstrate the dependence of the curvature ratio and the coercive force upon the orientation of the magnetic axis. Further, since both of these properties increase simultaneously in the region of the cube direction, there results a very marked improvement in the maximum energy. Although the table adequately summarizes these data, it was of interest to pursue the analysis to establish if the high and low values are approached asymptotically or whether there are cusps in the energy function. For this purpose, the data contained in Tables I to III were plotted on the unit stereographic triangle. Each set of data indicated a slow

Table VI. Crystal Orientation Effects

approach to the maximum value of the energy at the cube pole, but the data in the region of the octagonal pole were not conclusive.

When a saturating magnetizing field is removed, the directions of magnetization in the individual domains tend to return to the crystallographic axes of maximum stability, [100] in this case. If a cube axis is aligned with the direction of the magnetizing field, there will be relatively little loss in induction when the field is removed. Conversely, there will be a significant loss in induction if the crystallographic directions of easy magnetization are inclined at an appreciable angle to the axis of the magnetizing field. This concept suggests that the induction for any value of the applied field—and hence the energy product—should decrease continually as the angle between the magnetizing field and the crystallographic axis of easy magnetization is increased. Fig. 7 shows the result of fitting the simplest function of this type to the data obtained on all the Alnico 5 specimens. The scatter in the results is not excessive in view of the fact that the plot includes three separate sets of crystals which might be subject to composition and heat-treatment differences. This cosine relationship was adopted in the construction of a contour plot showing the variation in energy for all

Fig. 6—Distribution plot showing orientation of the cooling direction in a directionally chilled casting.

Fig. 7—Correlation of maximum energy values with the orientation of the magnetic axis in sintered crystals of Alnico 5.

intermediate orientations, Fig. 8. The nature of this energy relation is such as to produce flat maximums at the cube poles, saddles at the diagonal poles, and low cusps at the octagonal poles. This same construction was applied to the Alnico 6 data, and on the basis of the limited data, it appeared that the magnetic properties fell off somewhat more rapidly than a simple cosine law.

Grain Size Effects: Having obtained an estimate of the magnitude of the crystal orientation effects an attempt was made to apply these relationships to other phases of the problem. There is no preferred

Fig. 8—Contour plot showing relative values of the maximum energy for various orientations of the magnetic axis in sintered crystals of Alnico 5.

orientation in the fine, equiaxed grain structure of the normal sintered material which has an average grain diameter of 0.15 mm or an ASTM grain size of 2 to 3. Thus, if no factors other than the crystallographic orientation are involved, then the maximum energy of this material should be equal to the average value of the energy surface shown in Fig. 8. A mean value of 4,900,000 gauss-oersteds was obtained by a graphical integration of this figure in which the lateral contraction of the stereographic plot was considered by multiplying the unit areas by the cosine of the latitude. The fact that this calculated value is so much greater than the value of 3,500,000 usually obtained for sintered material suggests that a fine-grain structure may be detrimental *per se*, a conclusion which has been suggested by other observations.

For example, a similar analysis using a cast Alnico 6 contour plot yields an average value of 4,780,000

gauss-oersteds for randomly oriented polycrystalline material. This compares with a maximum energy of only 4,000,000 as measured on the fine-grained cast Alnico 6 specimen which had an average grain diameter of 0.5 mm, ASTM grain size -1, and is additional evidence of a detrimental grain size effect. This behavior is rationalized on the basis of the inherent instability of a fine-grained, multidomain structure. In such a structure the misalignment of the directions of easy magnetization between the neighboring grains will facilitate the formation of closed magnetic circuits within the material with a corresponding loss in the useful induction.

Columnar Grain Effects: In the light of these investigations it was of interest to review the original experiments on the columnar grain structures. The grain orientation survey definitely indicated the existence of a cube texture in this material. Actually a perfect alignment is not obtained in any cast texture, but rather the cube axes of all the grains will be distributed about the cooling direction. To characterize the degree of concentration of the cube axes about any given direction, it is convenient to think in terms of an equivalent, uniform distribution of cube axes confined to a cone of revolution about this chosen axis. The degree of concentration can be represented as the half angle of the cone which is required to produce the same resolved component of the [100] axes on this reference axis as exists in the actual casting. On the basis of the distribution plot presented in Fig. 6, it is estimated that the columnar grain structures could be represented by a half angle of 15°. Using this concept and the stereographic contour plots, the theoretical estimates of the fully aligned and the fully unaligned columnar grain structures can be compared. As shown in Fig. 9, the fully aligned structure would be represented by the average of all the energy values within a 15° cone about the [100] axis, while the cross aligned specimen would encompass all values within a 15° band on either side of the [100] zone. Using the same averaging procedure as before, the contour plots gave the values shown in Table VII.

Fig. 9—Method of estimating the relative energy values of two extreme types of columnar grain structures.

Table VII. Estimates of Columnar Grain Effects

Material	Fully Aligned	Cross Aligned	Difference
Alnico 5	5,790,000	5,180,000	610,000
Alnico 6	6,190,000	5,150,000	1,040,000

These crystallographic considerations predict an energy difference of a million gauss-oersteds or less between a casting composed completely of long columnar grains parallel to the magnetic axis and one in which all the grains are perpendicular.

Actually a much greater difference was found and therefore the columnar grain effects cannot be explained solely in terms of the crystal anisotropy. The remainder of this improvement may be a grain size effect. The "effective" grain sizes in a columnar grain casting were determined by measuring the mean distance between grain boundaries in two mutually perpendicular directions. Measuring parallel to the direction of growth, the distance between grain boundaries was found to average 3.0 mm, whereas in the perpendicular direction the mean path was only 0.4 mm. On the basis of these results, it appears that roughly two-thirds the improvement in the magnetic properties of a favorably aligned columnar grain structure may be attributed to the magnetic anisotropy factor, while the remainder is due to the reduction in the number of grains which are intercepted by the internal magnetic path.

Optimum Values: The values obtained in the [100] directions on these alloys are of special interest, since they demonstrate the degree of improvement which can be realized by proper control of the crystallographic variables. Table VIII presents a comparison of the best energy values obtained on the favorably oriented crystals along with the values that are usually quoted for these alloys.

Conclusions

1—Massive crystals of Alnico alloys can be produced either by the slow sintering of fine, non-oxidized powders or by the coarsening of relatively fine-grained castings.

2—The results obtained on single-crystal specimens show that the orientation of the magnetic axis has a marked effect on the performance of Alnico permanent magnets. The squarest demagnetization curves and the highest coercive force and maximum energy values are obtained in the cube direction, while the octagonal direction is the lowest in these respects. With a [100] magnetic axis, the maximum energy of sintered Alnico 5 crystals was about 6,000,000 gauss-oersteds which is appreciably greater than the [111] orientation value of 3,500,000 gauss-oersteds. Cast Alnico 6 crystals under similar circumstances gave values of 6,500,000 and 2,900,000 gauss-oersteds.

3—An analysis of the results obtained on single-crystal and polycrystalline specimens indicates that

Table VIII. Optimum Energy Values

Alloy	Nominal Value	Best Value
Sintered 5	3,500,000	6,320,000
Cast 6	4,000,000	6,550,000
Cast 5	4,500,000	7,590,000

the maximum energy value is reduced by a refinement in the grain size.

4—Cube textures are developed in castings of these alloys and desired orientations of this texture can be realized by the controlled extraction of the heat of solidification. A cast texture in which the columnar grains are aligned parallel to the magnetic axis will produce significantly higher maximum energies than the normal, randomly oriented, grain structure. These pronounced orientation effects can be explained partially on the basis of a cube texture coupled with the pronounced magnetic anisotropy and partially as the result of a larger effective grain size as measured in the direction of the magnetic axis.

5—A cube oriented, cast Alnico 5 crystal produced an energy value in excess of 7,500,000 gauss-oersteds.

Acknowledgment

The authors are indebted to the personnel of the General Electric Co. who supported or assisted in these programs over a three-year period. Particularly, we wish to acknowledge the support of Z. Jeffries and E. E. George who authorized certain phases of this work and the assistance of R. J. Studders for his invaluable contributions on the crystal preparation techniques. The many valuable discussions contributed by staff members of the Rensselaer Polytechnic Institute and the General Electric Research Laboratory contributed greatly to the progress of this work.

Vanadium-Uranium Constitutional Diagram

by H. A. Saller and F. A. Rough

Studies of the V-U system have been made to determine the constitutional diagram. The diagram is fairly simple, since no intermediate phases are formed. Additions of vanadium lower the uranium melting point and allotropic transformation temperatures. The maximum solid solubility of vanadium in uranium is 12 atomic pct and the maximum solid solubility of uranium in vanadium is about 4 atomic pct.

WITH the advent of high purity iodide vanadium,¹ it became of interest to study the alloying characteristics of vanadium and uranium. Alloys were prepared covering the entire system and were studied using a combination of metallographic examination and thermal and X-ray analyses. As a consequence of this work, the V-U constitutional diagram was evolved.

In order to prepare suitable alloys for equilibrium-phase studies, it is desirable to have the purest possible starting materials. For this investigation, calcium-reduced vanadium, de Boer process crystal-bar vanadium, and good Mallinkrodt Chemical Co. uranium were used. The first work was done using the best vanadium then available, that being calcium-reduced vanadium produced at Knolls Atomic Power Laboratory. Subsequently, the important features of the diagram were checked using alloys made with crystal-bar vanadium produced at Battelle. These checks are in agreement with the earlier work.

Analyses of the starting materials are contained in Table I. Only minor amounts of any impurities were present in either the vanadium crystal bar or uranium. Nevertheless, care was exercised in selecting the uranium for the alloys. The procedure followed was to section the stock into suitable pieces for melting, and macroetch each piece. Only those pieces which appeared to be clean by macroetch examination were used for alloying.

Experimental Procedure

Melting: Alloys with 0 to 50 atomic pct V were induction melted in beryllia (BeO) crucibles under vacuum of 10 microns pressure or better. A number of remelts was frequently required to insure uniformity of the individual ingots. Although no visible reaction between the alloy and crucible was found in any of these operations, the alloys were checked by spectroscopic analysis. Only trace amounts of beryllium were detected in the alloys.

Table I. Impurities in the Starting Materials

Element Detected	Uranium, Pct	Iodide Vanadium, Parts per Million
Fe	<0.01	150-250
Ni	<0.01	50
Al	<0.01	20-100
Mo	<0.01	50
Cr	<0.01	Trace
W	—	200
Cu	<0.01	50
V	<0.01	—
Si	<0.01	50-150
P	<0.01	—
Mg	<0.01	50
O ₂	—	280-370
H ₂	—	6-17
N ₂	—	40-60

Alloys containing 50 to 100 atomic pct V were arc melted in a water-cooled copper crucible under an atmosphere of helium. A tungsten electrode was used. Ingots of 10 to 15 g were produced readily by turning and remelting a few times. Such small ingots were necessary because high purity vanadium was not available in appreciable quantities at this time. After melting, the ingots were examined metallographically for segregation and were consolidated by remelting before fabrication was attempted. Spectroscopic analyses showed that only small amounts of tungsten were picked up during the arc-melting process.

Fabrication of Alloys: Alloys containing up to 20 atomic pct V could be fabricated by rolling in air at 600°C with 5 min between passes. After each pass through the rolling mill the alloys were returned to

Fig. 1—V-U constitutional diagram.

a furnace that had an atmosphere of argon. The alloys around 20 atomic pct V appeared to be less amenable to this procedure than were the lower alloys, however the fabrication was satisfactory for this work.

High vanadium alloys containing up to 10 atomic pct U were fabricated by jacketing in stainless steel and rolling at 1000°C with 5 min between passes through the rolling mill. No attempts were made to fabricate alloys of intermediate compositions, since preliminary work had shown that two-phase regions extended across the system with no intervening com-

pounds. It is expected that these intermediate two-phase alloys would also be workable, especially if jacketing techniques are used.

Sampling for Chemical Analysis: Samples for chemical analyses were cut from the top and bottom of each of the small induction-melted ingots of high uranium alloys. Since the high vanadium ingots were quite small, sampling techniques in this case were limited. Usually, whole metallographic samples of these alloys were submitted for analysis after thorough examination.

Heat Treating: All heat treating was done under vacuum of one micron pressure or better. The procedure followed was to homogenize the as-rolled alloys by soaking for 40 hr at 1000°C. Subsequent heat treatments at various temperatures were carried out as indicated in a later section of this paper.

Metallography: Specimens were cut using Allison, No. 46A3, cutoff wheels 0.020 in. thick. The samples were then ground wet through the usual rough papers and were finished wet on 240, 400, and 600 grit abrasives.

Alloys with 0 to 30 atomic pct V were polished and etched in a solution of chromic and acetic acids, Table II. Polishing was usually complete after 30 sec to 1 min at 50 v with a current density of approximately 20 amp per sq in. Etching was obtained by dropping the voltage to 6 to 10 v in the same solution. Relief, sometimes troublesome in two-phase alloys, was readily avoided by polishing mechanically with stannic oxide on a wheel covered with billiard cloth. This was followed by etching at 6 to 10 v in the chromic and acetic acid electrolyte. The same etch also served as a macroetch.

High vanadium alloys, 30 to 100 atomic pct V, were prepared for examination by grinding through the same series of abrasive papers, finishing on a billiard cloth with stannic oxide abrasive, and electropolishing for a few seconds at 10 to 20 v. The solution for this operation consisted of sulphuric acid and methyl alcohol. The exact composition is shown in Table II. This polish served to remove scratches and worked metal and also to etch two-phase alloys. Solid-solution-type high vanadium alloys were further etched by swabbing with a solution of hydrofluoric and nitric acids in water, Table

1 part concentrated HF
1 part H_2O

II. This etch brought out grain boundaries which were not visible after the electropolishing operation.

X-Ray Examination: A general survey of the alloy system was not made by X-ray examination. However, a number of confirming checks were made on the results of other studies by making X-ray diffraction patterns from metallographic sample surfaces.

Thermal Analysis: To determine solid-phase transformations, thermal analyses were performed on alloys across the constitutional diagram. Runs were also made for liquidus-solidus data on the high uranium alloys. Standard techniques of analysis were employed for this work using the differential-thermocouple arrangement.² The temperature differential between the neutral and active samples was plotted against the temperature of the active sample under test. Solid-phase transformations were then readily detectable in alloys containing appreciable amounts of a high uranium phase. Best results were obtained by cycling through transformation temperatures one or more times. The data obtained by heating appeared to be most reliable and were little affected by variations of heating rates between 1° and 5°C per min. Cooling data are not considered to be reliable, since difficulty was encountered with supercooling.

In all of this solid-phase work, the thermocouple bead was protected from the uranium by refractory insulators. A piece of refractory in the specimen hole prevented contact between the thermocouple bead and specimen, but allowed radiation directly between them. By using a fine wire, 30 gage thermocouple, this arrangement was found to give good sensitivity at the temperatures of testing.

The best data on the liquidus-solidus determinations were obtained by heating once through the melting range. After the first melting, alloys were usually segregated and unusable. During this work, the thermocouples were protected by using small specially prepared BeO protection tubes.

Results

Constitutional Diagram: The V-U constitutional diagram has been established and is shown in Fig. 1. Since no intermediate phases are formed, the diagram is relatively straightforward. It is characterized, generally, by a high temperature eutectic and lowering of the uranium allotropic transitions by additions of vanadium. The eutectic reaction occurs at $1040^\circ \pm 5^\circ\text{C}$ and 18 atomic pct V. The solubility of vanadium in γ uranium is a maximum of 12 atomic pct at the eutectic, and decreases to 9 atomic pct at the eutectoid temperature of $727^\circ \pm 5^\circ\text{C}$, Fig. 1. The β -uranium region is more restricted than the γ field with 2.0 atomic pct V being soluble at 700°C . The α region is restricted still further. In this case, a solubility of less than 1.5 atomic pct V at 600°C was found.

The solid solubility of uranium in vanadium is limited at all temperatures. The solid-solution line is a maximum at the eutectic temperature, Fig. 1. Here the solubility is 4 atomic pct, 15 wt pct, uranium. At lower temperatures somewhat lower solubilities were observed.

Microstructures of Cast Alloys: Many of the general features of the V-U system are apparent from the series of micrographs of as-cast alloys shown in Figs. 2 to 12. The first micrograph of the series, Fig. 2, shows the structure of arc-melted uranium. Addition of 7 atomic pct V alters the uranium structure producing primary uranium islands surrounded by transformed eutectic, Fig. 3. A somewhat similar structure is found in a 15 pct alloy, Fig. 4. However, in this case precipitation has occurred in the primary-uranium islands. In these two structures the eutectic was altered by the γ and β eutectoid transformations.

Primary dendrites of vanadium are present in a 20 atomic pct alloy indicating that it is on the vanadium-rich side of the eutectic composition, Fig. 5. Structures of additional alloys on the vanadium-rich side of the eutectic composition are shown in Figs. 6 and 7. The eutectic in these alloys is not evident as a two-phase structure. This is assumed to be due to precipitation of vanadium on the primary-vanadium particles during the eutectic reaction.

A decreasing or disappearing uranium phase is observed as the vanadium content increases from 80 to 97.5 pct, Figs. 8 to 11. In the 80 pct alloy considerable uranium-rich material is present while in the 95 pct alloy only scattered uranium-rich particles remain to be observed. A scattering of tiny particles of uranium-rich material also appears to be present in the 96.2 and 97.5 atomic pct alloys, Figs. 10 and 11.

Thermal Data: Some of the general features of the diagram have been illustrated by metallographic structures. As much, or perhaps more, data are also observable from a survey of thermal studies, Fig. 1. The eutectic, γ eutectoid, β eutectoid, and even approximate solubilities might be determined from these data alone, although the diagram is the result of combined studies.

Metallographic Studies of Solid Solubilities: The results of metallographic studies are summarized and plotted in Fig. 1. Data are shown for high uranium alloys quenched from temperatures of 1000° , 750° , 700° , 600° , and 450°C , and for high vanadium alloys from 1100° , 1000° , and 700°C .

Alloys for this work were homogenized by holding for 40 hr at 1000°C and quenching. Samples thus treated were held for appropriate times and quenched from the temperatures of interest. In determining the solubilities of vanadium in α uranium and of uranium in vanadium, the alloys were cold worked before heat treatment to accelerate the approach to equilibrium.

was allowed to proceed. Specimens withdrawn from the salt bath were quenched in cold water.

The progress of the transformation was followed by metallographic methods and also by the use of hardness measurements. Specimens were given a preliminary polish on broadcloth using No. 600 alundum, final polishing being on felt using magnesia at slow speed. The only etching reagent that produced satisfactory results was one containing: chromium oxide, 20 g; sodium sulphate, 1.5 g; and water, 100 ml. The etchant was applied by swabbing and gave better results for specimens transformed at lower temperatures when diluted with 5 parts of water.

Experimental Results

The nature of the isothermal transformation of the β phase changes with temperature although the change is gradual from near eutectoid temperatures, 440°C, to the alleged polymorphic transformation at 240°C. There are certain features of the transformation that are common to all temperatures in this range. These are as follows:

1—The β phase transforms sluggishly enough so that it can readily be retained at room temperature. The retained β is very coarse grained and is readily recognized microscopically by its salmon-pink color after etching. This makes the alloy appear pink to the naked eye. Since the β can be easily retained to room temperature,¹ it presumably also exists for a short time in the isothermal bath.

2—The large grained β then rapidly transforms into fine grained β'' * which can be recognized by its

* The following terminology will be used for the various phases formed in this Ag-Cd alloy:

- α — terminal solid solution, silver rich, face-centered cubic.
- β — high temperature intermediate solid solution, body-centered cubic.
- β'' — metastable transition phase, supposedly hexagonal close-packed.
- β' — equilibrium phase, ordered body-centered cubic.
- ζ — low temperature, equilibrium phase, hexagonal close-packed.

light yellow color. This change is accomplished by a pronounced drop in hardness, as shown in Fig. 2.

3—The fine grained β'' develops striations, as illustrated in Fig. 3. The striations seem to start at the grain boundaries and grow completely across the β'' grains. They are straight, parallel, and regularly spaced, usually only one set appearing in a β'' grain. They cause an increase in the hardness of the β'' as shown in Fig. 2. As the transformation temperature decreases, the striations become finer and more profuse as can be seen by comparing Figs. 3 and 8. At lower temperatures there is an increasing tendency for the striations to form along more than one set of crystallographic planes of the β'' giving less regular appearing striations. This is illustrated in Fig. 4. The striations are always associated with the light etching, yellow β'' .

4—Coincident with, or shortly after the striations appear in the β'' , a rejection of white α begins to take place as indicated in Fig. 5. This rejection decreases in amount with decreasing temperature of transformation and virtually ceases below 350°.

While the sequence of changes just described is common to the isothermal decomposition of β at all temperatures between 440° and 240°C, subsequent changes vary with temperature.

With further holding time in the range from about 440° to 400°C, the striations disappear and the amount of white α increases. This is shown in Fig. 6. At the same time the dark etching purple-pink colored phase, β' , appears in the regions where the striations have disappeared. Ultimately the striations and the β'' in which they originally formed disappear completely, the equilibrium structure of α and β' remaining. The equilibrium structure is shown in Fig. 7.

At about 400°C the striated β'' begins to break down by nucleation and growth of pearlitic ($\alpha + \beta'$) nodules, Fig. 8. Not all of the β'' is consumed by these nodules, some of the striations apparently developing the proper composition to form silver-rich α . When this composition is reached, an interface develops and the striations break away from the parent β'' , forming flat plates of white α . While this

Fig. 4—2 hr at 350°C. Striated β'' with some α at the boundaries. X250.

Fig. 5—30 min at 420°C. White α in striated β'' . X250.

Fig. 6—16 hr at 420°C. α in the form of Widmanstätten precipitate and as rounded particles. Matrix is residual striated β'' plus β' . X250.

Fig. 7—144 hr at 420°C. Almost all α and β' . Traces of β'' still exist. X250.

Fig. 8—30 min at 370°C. Pearlitic nodules growing in β'' . X250.

compositional adjustment is occurring, the remaining β'' is developing the composition of cadmium-rich β' . To complete the transformation, $\beta'' \rightarrow \beta'$, an ordering must also take place. Thus the final equilibrium structure in this temperature range of 400° to 350°C consists of α and β' , being similar to Fig. 7. It is interesting to note that no lamellar pearlite is ever found in the structure of this alloy after long holding times at any temperature. This pearlite does not spheroidize. It just gradually disappears, its place being taken by the Widmanstätten distribution of α in β' . When the transformation occurs in the neighborhood of 350°C, there seems to be less tendency for the β'' to transform by the nucleation and growth of pearlitic nodules. Instead, the decomposition of the β'' is by growth of the striations. They become wider, sharper, and better defined and ultimately develop a definite interface with the β'' matrix as shown in Fig. 9. At this point the striations

are readily seen to be α . While the striations are developing into α , the β'' matrix is transforming to β' in a very interesting manner. The yellow β'' first changes color to that of the purple β' , there being a definite color interface but not a phase interface. This is illustrated in Fig. 10. Then suddenly a discrete phase boundary appears where only the color interface previously existed. Fig. 11 shows α platelets, and the β' growing into the β'' . The $\beta'' \rightarrow \beta'$ reaction is only partially completed.

Around 300°C and below, the transformation of the striated β'' takes place entirely by the nucleation and growth of two phase ($\alpha + \beta'$) pearlitic nodules, Fig. 12. The pearlitic nodules consume the striations before they can become discrete α plates; the pearlite in turn giving way to the structure shown in Fig. 7.

It should be kept in mind that the change in the character of the transformation with decreasing tem-

peratures is gradual, there is no definite temperature where one transformation sequence is suddenly replaced by a different sequence. The time-temperature-transformation characteristics of the β phase for temperatures above 240°C are shown in Fig. 13.

As previously mentioned, the existence of a polymorphic transformation at 240°C is somewhat in doubt. Its existence was not confirmed in this work.

The transformation as just described, continues essentially unchanged down to about 234°C . When the eutectoid specimens are quenched into the isothermal bath below this temperature, only a part of the β quickly transforms into β'' , which is striated as formed, Fig. 14. Some thin platelets of α also appear within a few seconds. In about an hour at 200°C , pearlite nodules appear in the β'' as indicated in Fig. 15, and they grow until the β'' is entirely consumed. Once the β'' is consumed, there is no tendency for the growing pearlite nodule to grow into the surrounding β . This is shown in Fig. 16. During this time the α platelets start to spheroidize.

After the β'' has been consumed by the growing pearlite the remaining retained β transforms slowly to striated β'' , which in turn transforms to pearlite. While this β'' is transforming to pearlite, the pearlite which had formed previously is disappearing, its place being taken by the coarser Widmanstätten α in the β' and a structure similar to that shown in Fig. 7 is obtained.

The transformation was not followed to lower

temperatures because of the very long times required for transformation. The retained β is stable for at least 16 months at room temperature.

Discussion

Any mechanism for the eutectoid decomposition in this alloy must explain:

1—The isothermal formation of a fine grained, yellow etching β'' from a coarse grained, pink etching β .

2—The appearance of striations in the β'' , and the parallelism of the striations.

3—The disappearance of the striations with time, and the subsequent appearance of α platelets in a matrix of β'' or of two-phase nodules of α plus β' , depending on the temperature of transformation.

4—The transformation of the residual light etching β'' to the dark etching β' .

5—The fact that the β' , when first developed, differs in color from the β'' , but ultimately develops a sharp boundary with the β'' .

6—Why the pearlite nodules formed below 240°C consume only the β'' and do not continue growing into the surrounding β .

7—The continuous disappearance of lamellar pearlite with no evidence of spheroidization and the appearance of the coarser $\alpha + \beta'$ mixture in its place.

The mechanism of this eutectoid decomposition may be as follows: The high temperature, body-centered cubic β phase is retained by quenching into cold water. Some evidence of this is shown by the fact that etch pits on the surface of quenched specimens are cubic. Durrant¹ has also reported that the β phase, when quenched, shows no sign of decomposition. The β phase is also retained at high temperatures for a few seconds in the isothermal bath.

The β phase transforms rapidly by nucleation and growth into the metastable β'' in the temperature range of 440° to 240°C . This transformation explains the drastic change in grain size that the specimens undergo when held for only a few seconds in the latter temperature range. The presence of a metastable phase in the alloys near eutectoid composition has been reported by several investigators.^{2,4} There is however, some disagreement as to the true crystal structure of the metastable phase. It has been reported as hexagonal or rhombohedral⁴ and also as ordered body-centered cubic like the β' phase². The authors attempted some X-ray analysis of these structures, but were unable to successfully interpret the patterns obtained. It is not believed that the metastable phase is cubic; the structure of the meta-

stable phase is probably hexagonal. This is supported by the fact that etch pits in the β'' were indicative of a hexagonal structure.

The striations which appear in the β'' are probably the result of a "bainite-type" reaction of the type found in steels⁸ and certain Cu-Al alloys⁹. The "bainite" mechanism in this alloy may possibly be explained as follows:

1—The silver atoms segregate by diffusion to form regions in the β'' of high silver content surrounded by regions of low silver content. This is the point at which the striations first appear and coincides with the rapid increase in hardness, Fig. 2.

2—The β'' of high silver content usually transforms into α platelets above 300°C. At lower temperatures the striated β'' transforms only into pearlite ($\alpha + \beta'$).

3—Above 350°C the residual β'' matrix then transforms into β' .

It may be asked why the striations should appear on only one set of crystallographic planes of the β'' . A possible explanation of this phenomenon is that given by Barrett¹⁰ in his discussion of Widmanstätten precipitates. If it is assumed that the striations are concentration gradients which are formed prior to the precipitation of α , and that the metastable β'' is hexagonal close-packed, then it would be expected that the striations would form on only one set of crystallographic planes of the β'' . This is due to the fact that the (111) plane in the α (face-centered cubic) and the basal plane in the β'' (hexagonal close-packed) are planes of closest matching. A precipitate of α on the basal plane of the β'' would therefore be anticipated, since precipitation takes place in such a way that matched planes occur at the matrix-precipitate interface. The striations form on the same planes where the α is going to precipitate. This may explain the formation of α and striations on preferred crystallographic planes. This, however, does not explain the formation, in some cases, of Widmanstätten needles of α on crystallographic planes different from those on which the striations form, Fig. 6, nor the tendency to form more than one set of striations within a single β'' grain at transformation temperatures below 300°.

Above 300°C the striations transform into α platelets. At this and lower temperatures, however, the striations do not form platelets, but are consumed by two phase pearlitic nodules. This means that at about 350°C the surface energy requirement of a platelet cannot be met and therefore it does not form. The pearlite which consumes the striations at these temperatures is in turn replaced by a structure of lower energy, coarse $\alpha + \beta'$.

The consumption of the β'' by the β' is an ordering reaction. The type of reaction suggested in this paper, $\beta \rightarrow \beta'' \rightarrow \beta'$, has also been suggested by Kosolapov and Trapeznikov⁴. The presence of only a color boundary between the β'' and β' probably indicates that the necessary adjustment in chemical composition has been made but coherency still exists between the two phases. As the β'' becomes ordered, coherency is lost and a sharp interphase boundary is formed.

Item 6, given previously, relating to the fact that below 234°C the growing pearlite nodule will consume only the striated β'' and will not continue growing into the surrounding β is a very important observation on the growth of this pearlite. The α rim which forms around the β'' , Fig. 16, and which might be considered as a mechanical obstruction to the

growth of the pearlite is not the important factor. Areas in the structure can be found where this α rim fails to form and yet the growing pearlite stops at the β'' - β interface. This results from inherent differences of the β and β'' .

The fact that the lamellar pearlite continuously disappears in favor of a coarser aggregate of α and β' has also been observed in other eutectoid alloys. This phenomenon has an important bearing on the morphology of the pearlites and will be discussed in detail in another paper.

Summary

The isothermal transformation of the Ag-Cd eutectoid alloy has been studied at subeutectoid temperatures. Although certain features of the transformation, i.e., retention of the high temperature β , its subsequent transformation to fine grained β'' and the formation of silver-rich striations in the β'' are common to all temperatures below 440°C, the subsequent features of the transformation change with temperature. At high temperatures the striated structure disappears forming a heavy Widmanstätten pattern of α in β' ; around 370°C, the striated β'' begins to decompose by nucleation and growth of pearlite as well as by the formation of α platelets from the striations. Below 300°C the transformation takes place only by means of the pearlite reaction. But at all temperatures, the final result is the same, a coarse structure of α in β' .

The presence of the polymorphic transformation at 240°C was not confirmed by the metallographic methods employed.

Acknowledgment

The authors wish to express their appreciation to R. B. Caples, of Anaconda Copper Mining Co., who donated the cadmium for this study; for the advice of V. W. Meloche, of the Chemistry Department, in regard to the chemical analysis of the alloy; for the financial assistance of the Wisconsin Alumni Research Foundation, under RF50:315, to carry out this investigation; for the aid of R. C. Wiggins in the construction of the experimental apparatus; and for the helpful criticism offered by S. A. Kulin.

Kinetics of the Oxidation of Galena in Sodium Hydroxide Solutions Under Oxygen Pressure

by J. E. Andersen, J. Halpern, and C. S. Samis

In the presence of oxygen, galena is oxidized in an aqueous medium containing sodium hydroxide, in accordance with the following reaction:

A novel method was devised for following this reaction which takes place in an autoclave under oxygen pressure, by measuring the concentration of HPbO_2^- in the solution with a cathode ray polarograph employing stationary platinum electrodes. Using this procedure a study was made of the kinetics of the reaction, in which the effect of a number of variables, including temperature, oxygen pressure, NaOH concentration, and agitation, on the rate, were determined. The results of this study are described and discussed, in terms of possible mechanisms for the reaction.

IT is known that sulphide minerals can be oxidized in aqueous media in the presence of oxygen under pressure. Reactions of this type can be classified in two categories depending upon whether the products of oxidation are insoluble or soluble in the aqueous medium. An example of the first type of reaction is the oxidation of pyrite in alkaline solutions, giving rise to an insoluble iron oxide. The kinetics of this reaction have been investigated and its mechanism established.¹ It has been applied in the oxidation of iron sulphides present in refractory gold ores to improve the subsequent recovery of gold by cyanidation.² The second type of reaction finds application where it is desired to recover the metal by leaching during oxidation. In this case a medium is selected in which the oxidized mineral is soluble. For example, nickel, copper, and cobalt sulphide ores can be treated by oxidation in the presence of a solution of ammonia dissolving the nickel, copper, and cobalt as the metal ammine sulphate salts.³ A similar treatment has also been reported to apply to zinc sulphide ores.⁴

It is known that lead sulphate is soluble in solutions of sodium hydroxide or ammonium acetate. It should therefore be possible to dissolve the lead from galena ores by aqueous oxidation with oxygen under pressure using either of these solutions. The applicability of the ammonium acetate treatment has been investigated and confirmed in a recent study.⁵

The present paper describes the results of a similar study in which the kinetics of the oxidation of galena in sodium hydroxide solutions have been investigated. The object of this investigation was pri-

marily to obtain information of a fundamental nature relating to the kinetics and mechanism of this reaction.

The use of pulps of comminuted ore in a study of this type is undesirable because of the difficulty in controlling and measuring the surface area. The measurements were therefore made using galena crystals of measured surface area and in this way absolute reaction rates were obtained.

The reaction was found to proceed as follows:

The products are sodium plumbite and sodium sulphate salts which dissolve in the aqueous solution.

The reaction studies were carried out in an autoclave in which a desired pressure of oxygen was maintained. The reaction was followed by measuring the concentration of lead in the solution with a cathode ray polarograph. The results obtained in this investigation are presented and discussed in the present paper.

Experimental

Materials: The crystals of galena were obtained from Violamac Mines, Sandon, B. C. The following impurities were indicated by spectrographic analysis carried out by the Provincial Assay Office, Victoria, B. C.: Sn, 0.02 to 0.2 pct; Sb, 0.07 to 0.7; Zn, 0.01 to 0.1; Si, Fe, Mg, As, less than 0.05 pct; Ag, 126 oz per ton, the latter determined by standard fire-assaying procedure.

After cutting a specimen measuring approximately 5x7x12 mm, the crystal surfaces were ground parallel to the 100 axes using No. 2 emery, washed with water, and the dimensions were measured with a micrometer. Oxygen gas was of commercial grade and supplied in cylinders by Canadian Liquid Air. Solutions were made up with chemicals of chemically pure grade and distilled water.

Equipment: Autoclave: The autoclave used in these studies was constructed of stainless steel and

J. E. ANDERSEN is Graduate Student and Holder of the Cominco Fellowship, J. HALPERN is Assistant Professor of Metallurgy, and C. S. SAMIS is Associate Professor of Metallurgy, Dept. of Mining and Metallurgy, The University of British Columbia, Vancouver, B.C., Canada.

Discussion on this paper, TP 3407D, may be sent, 2 copies, to AIME by June 1, 1953. Manuscript, June 9, 1952; revised, Dec. 1, 1952. Spokane Regional Meeting, May 1952.

is shown schematically in Fig. 1. The inside dimensions were 2 in. diam x 6 in. high. The autoclave was equipped with a thermometer well and an external heating jacket. The contents were stirred with a cylindrical steel rotor, driven by a 2.5 in. Alnico magnet, rotated externally below the autoclave. The speed of rotation could be varied from 80 to 250 rpm. A Bourdon gage was used to measure the pressure.

Polarograph: The cathode ray polarograph used to determine the concentration of lead in the solution, as the reaction proceeded, was essentially similar to that described by Randles,⁶ and included a cathode ray oscilloscope to amplify and record the vertical (current) and horizontal (voltage) signals. Additional units included an electronically stabilized

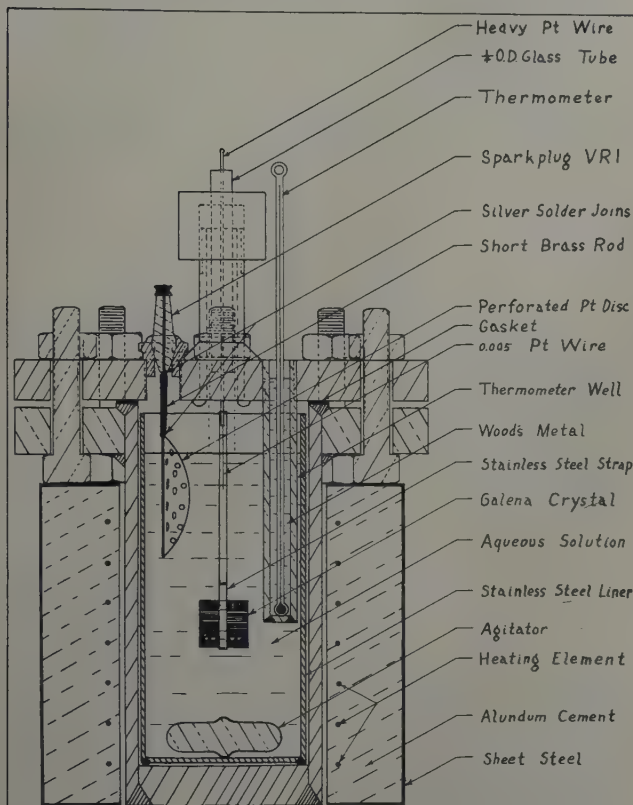

Fig. 1—Schematic drawing showing construction and parts of the autoclave.

voltage supply and a synchronizing unit to control voltage sweep.

The use of a dropping mercury electrode was not feasible under the experimental conditions used (i.e., in an autoclave under pressure) and stationary electrodes were substituted. A small bead of platinum at the end of a 3 mm length of 0.1 mm platinum wire immersed in the solution constituted the polarizable micro electrode (cathode). The unpolarized electrode (anode) was a 2.5 cm disk of perforated platinum foil. Each electrode was connected to an insulated platinum wire which was sealed through the top of the autoclave.

The theory relating to the use of this instrument is given by Randles.⁷ A rapid voltage sweep (about 1 v per sec) was used with an interval of 10 to 15 sec between sweeps. A drawing of a typical polarogram is shown in Fig. 2. The height of the lead peak, measured from the level of the preceding oxygen wave, as indicated in the figure, is proportional to the concentration of HPbO_2^- in solution. The valid-

Fig. 2—Drawing of a typical polarogram showing peaks corresponding to oxygen and lead.

ity of this analytical method was confirmed by experimental calibration.

Experimental Procedure: 155 milliliters of an aqueous solution of sodium hydroxide of the desired concentration was placed in the autoclave and a crystal of galena, prepared as described earlier, was mounted in a stainless steel holder and suspended below the surface of the solution in the autoclave. The stirrer was turned on and the autoclave heated to a desired temperature. A desired pressure of oxygen was introduced and maintained. Polarograms were obtained at 15 min intervals by photographing the oscillograph screen. At the end of the experiment the concentration of lead in the solution was determined by the ammonium molybdate gravimetric method. This value was used to calibrate the polarographic measurements. Rate curves were plotted, using values for the concentration of lead determined from the polarograms.

Results and Discussion

Reaction Products: Analysis of the solutions indicated that equimolar concentrations of $\text{SO}_4^{=}$ and HPbO_2^- were formed during the reaction. No other forms of lead or sulphur were observed in the solution. The reaction appears to be represented accurately by Eq. 1.

After the reaction, the crystal surface generally showed some etching in the form of lines and pits, apparently formed by intersecting 111 planes. A

Fig. 3—Micrograph of galena crystal after oxidation in 0.5N NaOH at 150°C for 200 min. X35.

Fig. 4—Typical rate curve for the oxidation of a galena crystal.

micrograph illustrating this effect is shown in Fig. 3. In general there was no evidence of a phase change (formation of solid products) on the galena surface. In a few cases where high NaOH concentrations were used, a loosely adherent yellow coating, believed to be hydrated PbO, was observed to form after cooling.

The Rate Curves: A typical rate curve for the reaction is shown in Fig. 4. An initial induction period was generally present and is believed to be due to the slow dissolution of an oxidized film on the galena surface formed during exposure to air and polishing of the crystal.

Following this induction period, the rate curves were generally linear for the duration of the experiments (60 to 300 min). Reaction rates were calculated from the slopes of these linear plots. It was found that under given experimental conditions, this rate was proportional to the surface area of the galena crystal used. This is shown in Table I. The amount of galena dissolved during any experiment was small, in all cases less than 4 pct of the initial weight of the crystal, so that the apparent surface area remained substantially constant during each experiment. This accounts for the linear reaction rate curves. Reaction rates determined in this way were found to be reproducible to within ± 5 pct even when different galena crystals were used.

Effect of Oxygen Partial Pressure: Experiments were made at 123°C in 0.5N NaOH, using different partial pressures of oxygen ranging from 0 to 11 atm. The results are shown in Fig. 5.

It is seen that the rate of oxidation and solution of galena is proportional to the square root of the partial pressure or concentration of oxygen. This indicates that the oxygen participating in the rate controlling step of the reaction is in a dissociated state.

Table I. Rate of Oxidation of Galena in NaOH Solution

NaOH concentration — 0.5 mols per liter Temperature — 149° C O ₂ partial pressure — 83 psi (5.64 atm) Stirrer speed — 48 cm per sec

	Mg per Min	Mg per Sq Cm per Min	Mols per Sq Cm per Sec	Deviation, Pct
4.02	0.845	0.210	1.47×10^{-3}	+2.1
4.56	0.935	0.205	1.44×10^{-3}	0
8.71	1.745	0.204	1.42×10^{-3}	+1.4
Mean value		0.206	1.44×10^{-3}	

Effect of Sodium Hydroxide Concentration: The effect of the sodium hydroxide concentration on the kinetics of the reaction was investigated in a series of experiments at 149°C. The concentration of NaOH was varied from 0.5 to 6N. The results are given in Table II and plotted in Fig. 6, using arbitrary units.

It was found that increasing the concentration of NaOH from 0.5 to 6.0N results in a marked lowering of the reaction rate. The shape of the curve is similar to that depicting the change in the square root of the solubility of oxygen with increased NaOH concentration at 25°C, also shown in Fig. 6 and based on data by Geffcken.⁸ The similarity of the two relations suggests that the effect of NaOH on the rate can be at least in part accounted for by the decreased solubility of oxygen with increasing NaOH, since it has already been established that the rate is proportional to the square root of the concentration of oxygen.

Effect of Stirring: The effect of the stirrer velocity on the reaction rate is also shown in Table II and

Fig. 5—Effect of the pressure of oxygen on the rate of oxidation of a galena crystal. Solution 0.5N NaOH. Temperature 123°C.

Fig. 6. At low concentrations of NaOH (0.5N) it was found that varying the velocity of the stirrer from 9 to 48 cm per sec had no effect. At higher NaOH concentrations, however, the rate increased markedly with the stirring speed. This effect can be explained in terms of the increase in the viscosity of the medium at higher NaOH concentrations, lowering the rate of diffusion of oxygen to the galena surface. The concentration of oxygen at the reacting surface becomes depleted and the reaction rate is controlled in part by the transport of oxygen to the surface, the rate of which depends on stirring. At low NaOH concentrations the transport of oxygen to the surface is more rapid and the rate of reaction becomes activation controlled and independent of the stirring velocity.

A more quantitative correlation of these effects is impossible in the absence of data relating to the solubility of oxygen and the viscosities of the solutions under the conditions used.

Effect of Temperature: The effect of temperature on the rate of reaction was investigated in the range 93° to 175°C using a 0.5N NaOH solution and an oxygen partial pressure of 5.64 atm. A concentration of 0.5 NaOH was selected for the study of this variable since it has already been demonstrated that under these conditions the reaction rate and therefore the measured activation energy is independent of the stirring velocity.

A good Arrhenius plot was obtained as shown in Fig. 7. The slope corresponds to an apparent activation energy, E , of 6300 cal per mol.

Conclusions

Summary of Kinetic Results: The kinetic results, described above, permit the following conclusions to be drawn regarding the mechanism of the reaction and the nature of the slow or rate controlling stage.

1—The rate controlling step of the reaction is a heterogeneous process occurring at the galena surface and not a homogeneous reaction in solution. This is indicated by the fact that the rate is proportional to the galena surface area.

2—Although four atoms of oxygen are involved in the overall oxidation of one molecule of PbS (Eq. 1), only one atom participates directly in the rate controlling step. This is indicated by the dependence of the rate on the square root of the oxygen pressure.

3— NaOH has only a secondary effect on the kinetics of the reaction, arising from its influence on the solubility and transport of oxygen in the solution. Although OH^- occurs as a reactant in the equation

Fig. 6—Effect of the concentration of NaOH on the rate of oxidation of galena and on the solubility of oxygen. Temperature 149°C . O_2 partial pressure 5.64 atm.

tion for the overall reaction, it does not appear to participate directly in the rate controlling step, over the range of conditions investigated.

4—Water is known to participate in the reaction, since the products are hydrated ions. This reactant cannot be studied as a kinetic variable since its concentration remains effectively constant. However the participation of water in the rate controlling step is indicated by quantitative examination of the kinetic data as shown later.

5—The activation energy for the reaction is 6300 cal per mol.

6—The experimental results show that the transport of oxygen through the solution to the galena surface or the diffusion of reaction products away from the surface do not constitute the rate determining steps under the experimental conditions used, although they may influence the rate at high NaOH concentrations.

7—The rate controlling step of the reaction may involve the oxidation of a lead and sulphur atom simultaneously or alternatively the oxidation of only one of these followed by rapid reaction of the other. Both these possibilities are consistent with the observed fact that the lead and sulphur are always oxidized and dissolved in equimolar concentrations and it is impossible to distinguish between them on the basis of the kinetic measurements.

Proposed Mechanism of the Reaction: A mechanism

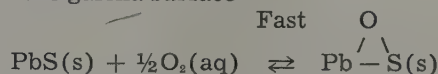

Fig. 7—Arrhenius plot showing the effect of temperature on the rate of oxidation of galena. Solution 0.5N NaOH . O_2 partial pressure 5.64 atm.

nism for the overall reaction involving the following sequence of steps is consistent with all these observations:

Step 1: Solution of gaseous oxygen in the aqueous medium

Step 2: Adsorption and dissociation of oxygen on the galena surface

Step 3: Hydration of oxygen atom adsorbed on galena site

Step 4: Formation of reaction products

Overall reaction:

The states of the reacting species are represented by the following symbols: (g), the gaseous state; (l), the liquid state; (s), the solid surface state; and (aq), the aqueous solution.

In the above sequence, steps 1 and 2, the solution of oxygen and its chemisorption on galena sites are assumed to be reversible, the equilibrium in each case being rapidly established. The fraction of

Table II. Effect of NaOH Concentration and Stirrer Velocity on the Rate of Oxidation of Galena

Temperature — 149°C
 O_2 partial pressure — 5.64 atm

Stirrer Velocity Relative to PbS Surface	NaOH Concentration	Rate Constant (K) Mols $\text{Cm}^{-2} \text{Atm}^{-1/2} \text{Sec}^{-1}$
9 cm sec^{-1}	0.5N	6.17×10^{-9}
	3 N	2.44×10^{-9}
	6 N	0.53×10^{-9}
	0.5N	6.17×10^{-9}
48 cm sec^{-1}	3 N	3.47×10^{-9}
	6 N	2.01×10^{-9}

galena sites covered with oxygen is small. Step 3 is the slow stage, determining the rate of reaction. The activated complex is formed through the reaction of water with a galena site on which an oxygen atom is adsorbed. The further oxidation of this complex and the formation of the observed products by reaction with OH^- (step 4) then follow rapidly.

The Eyring theory of absolute reaction rates⁹ expresses the rate of a chemical reaction as follows:

$$\text{Rate} = \frac{kT}{h} C_1 C_2 \frac{\gamma_1 \gamma_2}{\gamma^\ddagger} \exp \left[\frac{-\Delta F^\ddagger}{RT} \right] \quad [2]$$

where k is the Boltzmann constant; h , Planck's constant; C_1 and C_2 are the concentrations of the reactants; γ_1 and γ_2 , the corresponding activity coefficients; γ^\ddagger is the activity coefficient of the activated complex; and ΔF^\ddagger , the free energy of activation.

Application of this equation to the rate controlling step (step 3) in the above sequence gives the following expression for the specific rate constant per unit area of galena surface. As a first approximation the activity coefficients have been assumed to be equal to unity.

$$\text{Rate} = \frac{d(\text{PbS})}{dt} = \frac{kT}{h} C_{\text{O}}^{\text{Pb-S(s)}} C_{\text{H}_2\text{O(l)}} \exp \left[\frac{-\Delta F^\ddagger}{RT} \right] \quad [3]$$

where (PbS) is the number of mols of PbS reacted in time, t ; ΔF^\ddagger , the free energy of activation ($= F^\ddagger - F_{\text{O}}^{\text{Pb-S(s)}} - F_{\text{H}_2\text{O(l)}}$); $C_{\text{H}_2\text{O(l)}}$, the concentration of liquid water; and $C_{\text{O}}^{\text{Pb-S(s)}}$, the concentration of oxygen atoms chemisorbed onto galena surface sites.

The concentration term, $C_{\text{O}}^{\text{Pb-S(s)}}$, can be obtained in the following form by thermodynamic consideration of the equilibria involved in steps 1 and 2:

$$C_{\text{O}}^{\text{Pb-S(s)}} = C_{\text{PbS(s)}} C_{\text{O}_2(\text{g})}^{1/2} \exp \left[\frac{-\frac{1}{2}(\Delta F_1 + \Delta F_2)}{RT} \right] \quad [4]$$

where $C_{\text{PbS(s)}}$ and $C_{\text{O}_2(\text{g})}^{1/2}$ are the concentrations of galena surface sites and of gaseous oxygen molecules, respectively; ΔF_1 is the standard molar free energy of solution of gaseous oxygen in the aqueous solution, i.e., of step 1 ($= F_{\text{O}_2(\text{aq})} - F_{\text{O}_2(\text{g})}$); and ΔF_2 , the standard molar free energy of adsorption of dissolved oxygen on galena, i.e., of step 2 ($= 2F_{\text{O}}^{\text{Pb-S(s)}} - 2F_{\text{PbS(s)}} - F_{\text{O}_2(\text{aq})}$).

Combining Eqs. 3 and 4 gives the following expression for the specific reaction rate:

$$\text{Rate} = \frac{kT}{h} C_{\text{PbS(s)}} C_{\text{O}_2(\text{g})}^{1/2} C_{\text{H}_2\text{O(l)}} \exp \left[\frac{-(\frac{1}{2}\Delta F_1 + \frac{1}{2}\Delta F_2 + \Delta F^\ddagger)}{RT} \right] = \quad [5]$$

$$\frac{kT}{h} C_{\text{PbS(s)}} C_{\text{O}_2(\text{g})}^{1/2} C_{\text{H}_2\text{O(l)}} \exp \left[\frac{-(F^\ddagger - F_{\text{H}_2\text{O(l)}} - \frac{1}{2}F_{\text{O}_2(\text{g})} - F_{\text{PbS(s)}})}{RT} \right] = \quad [6]$$

$$\frac{kT}{h} C_{\text{PbS(s)}} C_{\text{O}_2(\text{g})}^{1/2} C_{\text{H}_2\text{O(l)}} \exp \left[\frac{\left[\frac{(S^\ddagger - S_{\text{H}_2\text{O(l)}} - \frac{1}{2}S_{\text{O}_2(\text{g})} - S_{\text{PbS(s)}})}{R} \right] - \left[\frac{-(H^\ddagger - H_{\text{H}_2\text{O(l)}} - \frac{1}{2}H_{\text{O}_2(\text{g})} - H_{\text{PbS(s)}})}{RT} \right]}{RT} \right] \quad [7]$$

since $F = H - TS$

where S , H and F are the standard entropies, enthalpies, and free energies of the denoted species.

Eq. 7 can be further expressed in terms of the experimental activation energy, E , as follows:⁹

$$\text{Rate} = e^2 \frac{kT}{h} C_{\text{PbS(s)}} C_{\text{O}_2(\text{g})}^{1/2} C_{\text{H}_2\text{O(l)}} \exp \left[\frac{S^\ddagger - S_{\text{H}_2\text{O(l)}} - \frac{1}{2}S_{\text{O}_2(\text{g})} - S_{\text{PbS(s)}}}{R} \right] \exp \left[\frac{-E}{RT} \right] \quad [8]$$

Assuming the entropies of the solid surface states (i.e., S^\ddagger and $S_{\text{PbS(s)}}$) to be equal to zero (since these correspond to vibrational degrees of freedom only, their values will be negligible in comparison with the other terms) and evaluating the remaining terms in Eq. 8 by standard procedures, the rate of reaction at 123°C is calculated to be

$$6.5 \times 10^{-6} \text{ mols cm}^{-2} \text{ atm}^{-1/2} \text{ sec}^{-1}$$

The experimentally observed rate under these conditions is

$$4.2 \times 10^{-6} \text{ mols cm}^{-2} \text{ atm}^{-1/2} \text{ sec}^{-1}$$

This agreement between the observed and calculated values of the rate is considered very good in view of the approximations involved in the calculations and lends further support to the general mechanism which has been proposed, in which the rate controlling step is the reaction of a water molecule with a galena surface site on which an oxygen atom is adsorbed.

Formation of Deformation Bands

In Al-3 Pct Mg Monocrystals

During Cold Rolling

by J. Herenguel, P. Lacombe, and P. Lelong

IN previous studies on the effect of orientation on the rate of anodic oxidation of Al-3 pct Mg monocrystals of high purity, certain anomalies were observed on the cold-worked metal. These anomalies were shown to correspond to regions of changed orientation within the grains resulting from plastic deformation.¹ In fact, they are deformation bands revealed by differences in rate of oxidation and produced by more or less continuous bending of the lattice about a [111] axis common to the original crystal and the band.^{2,3} Preliminary observations made after relatively large degrees of cold working revealed an approximate twin relationship between the bands and the surrounding crystal. Fig. 1 shows the etch figures formed on such a band and on the original monocrystal after a 67 pct rolling reduction. It is evidently not a true twinning, since there is a broad transition zone between the two systems, however the two extreme orientations are nearly in a twin relationship.

It was decided to investigate these preliminary observations by progressive rolling-reductions on monocrystals of varied initial orientation. From these studies, which form the subject of the present article, it became apparent that the initial observation of an approximate twin relation between the bands and the monocrystal was simply a special case.

Our experiments show that deformation in rolling proceeds by a mechanism analogous to those which have already been observed in the simpler cases of tension and compression. Micrography—in particular, the formation of etch figures—has been applied to the quantitative study of these orientations. In addition, observations have been made of slip lines, of thin oxide films yielding interference colors, of thick films in polarized light, and of etchants giving “engraving.” These micrographic methods for studying orientation have established the orientation relationship without any ambiguity, whereas X-ray methods would have given only a statistical result

Fig. 1—Al-3 pct Mg monocrystal cold rolled 67 pct and etched for etch-figures. The two extreme portions A and B, in near-twin relation, are connected by a zone of transition pits. X600. Area reduced approximately 50 pct for reproduction.

because we were often dealing with thin bands (2 to 100 microns) and even narrower connecting zones covering a maximum of 20 microns.

Specimen Preparation and Methods

The Al-3 pct Mg alloy was prepared from 99.95 pct Al and is of the type used industrially in France for brilliant anodized finishes under the name of Brillalumag. This material combines the normal commercial properties with an enduring brilliance due to the protection of a thick, but perfectly transparent, film of alumina.⁴

The monocrystals were prepared by the method of critical deformation followed by prolonged annealing. Great care was taken to insure perfect homogeneity of composition, to eliminate included crystals,^{6,7} and to avoid the formation of undulations during oxidation.⁵ The critical deformation for this alloy is about 1.2 pct ($(l-l_0/l_0 \times 100)$) and the subsequent annealing was for one week at 500°C after gradual increase of temperature (35°C per hr). The crystals thus prepared had a section of 10x5 mm and a length of 20 to 40 mm. Each of these crystals was polished electrolytically and etched for the formation of etch-figures with the classical reagent.⁸ The orientation was then calculated from their angles, as measured with a goniometer microscope.

Fig. 2—Stereographic projection on a (100) plane showing the poles of the plane and direction of rolling for crystals A, B, C, and D. Solid circle, pole of the rolling plane. Open circle, pole of the rolling direction.

Rolling was done with cylindrical rolls of 100 mm diam which were degreased before each operation with trichloroethylene. The roll gap was closed progressively and observations were made after each stage. The specimens were always introduced in the rolling mill by the same end and the cold-work required was obtained by several passes.

For microexamination, the specimens were polished mechanically and finished electrolytically. They were then etched for the formation of etch-figures with the reagent maintained at an optimum temperature of 7° to 8°C. For observations on thin oxide films, anodic oxidation was carried out under conditions already published.⁹ For thick films, oxidation was effected in sulphuric acid (10 pct by volume) at a current density of 1 amp per sq dm for 30 min at 20°C. Etching for "engraving" was produced by the action of the electrolytic-polishing mixture of phosphoric-sulphuric acids at 60° to 70°C without applied current,⁶ or alternatively by 20 pct caustic soda at 40° to 50°C. Such etching gives a surface appearance which depends on orientation and can be profitably examined in polarized light.

Experimental Results

Several crystals were cold-rolled. The results on each will be described at successive stages of reduction.

Fig. 3—Appearance of crystal A etched for etch-figure formation after 10 pct reduction. Note the lines which cross the micrograph diagonally. X1000. Area reduced approximately 50 pct for reproduction.

Crystal A: The orientation with respect to the plane and direction of rolling is shown in Fig. 2 which also gives that of the other crystals. The following phenomena were observed as a function of cold working.

1—Rolling Reduction 5 to 10 Pct: Slip lines were visible on the surface of the specimen. After electrolytic polishing of the rolled surface, no local regions of changed orientation were found by any of the different micrographic methods. However, after 10 pct reduction, there appeared certain lines different in character from the classical slip lines. They reappeared even after several successive polishings (removing 0.02 to 0.03 mm of metal) and became more pronounced after etching for the formation of etch-figures, Fig. 3. In addition, they were parallel to the trace of a (111) plane—a plane which later plays an important role.

2—Rolling Reduction 18 Pct: The lines seen after 10 pct reduction disappeared completely but deformation bands began to appear. None of them completely traversed the width or thickness of the specimen, and they were visible on only one of the two rolled surfaces after the different etching treatments.

These bands may be defined in the following manner: the orientation relationship between them and

Fig. 4—True position of deformation bands of crystal A as seen in the rolled surface after 18 pct reduction. Sketch magnified approximately 3 times.

the surrounding crystal corresponds to a rotation of 5° to 7° around a [111] axis, which lies almost in the rolling plane and makes a large angle with the rolling direction. The interface between band and crystal was parallel to a (110) plane of the actual crystal, this having been established by observations on two perpendicular faces—the rolled surface and the lengthwise surface. This (110) plane contains the [111] axis of rotation which makes the initial crystal pass from its orientation to that of the bands. In the present case, this (110) plane was slightly inclined to the rolling plane. Figs. 4 and 5 illustrate these observations.

The bands had a thickness covering the range of 5 to 75 microns but were often 30 microns thick. The connecting zones spread over 1 to 2 microns rendering their analysis impossible at this stage of rolling.

3—Rolling Reduction 25 Pct: Increased change, corresponding to rotations up to 10°, and a slight broadening of the transition zones were observed. However, no new bands appeared.

4—Rolling Reduction 45 Pct: The original system of bands continued to change and other systems appeared.

Within the original bands, further local changes of orientation occurred by a mechanism identical

Fig. 5—Diagram showing how the cube representing the crystal lattice in its initial position is oriented with respect to the plane and direction of rolling. Note the conspicuous position of the (110) interface plane and of the [111] axis of rotation. "Ephemeral line" is that observed after 10 pct reduction but which later disappears.

Fig. 6—Diagram showing the formation of a primary band and of a secondary band by double curvature about a [111] axis normal to the paper, becoming localized on a (110) plane.

with that which functioned initially; that is, by rotation about a [111] axis which is therefore common to the original crystal in its present position, to the primary band, and to the secondary band which it contains.

The rotation was 17° between the initial crystal and its primary bands, and 13° between the primary bands and their secondary bands. The total rotation between secondary bands and the initial crystal was thus $13^\circ + 17^\circ = 30^\circ$.

The interface between primary and secondary bands is the (110) plane of the primary band lattice which still contains the [111] axis of rotation. Thus in the diagram of Fig. 6, the plane of the paper is the (111) plane perpendicular to the [111] axis of rotation. The [110] axes which are in fact curved in the connecting zones by the mechanism of band formation are also shown. Fig. 7, taken in polarized light, shows the actual appearance of the surface after "engraving."

The connecting zones between the primary bands and initial crystal now became wider and reached about 6 microns. At high magnifications, these zones were seen to be finely striated in saw-tooth form, of the order of one micron, Fig. 8.

New systems appeared, though on a scale much smaller than the previous ones, but this time covering the whole of the specimen. It was possible to distinguish:

a—Certain systems close to the primary bands and between them. These consisted of thin lamellae (10 microns) of slightly differing orientation (2° to

3°) and regularly alternating. Their interfaces were still straight but it was not possible to identify their direction in relation to the lattices, nor the mode of rotation. Fig. 9 shows such complex systems after "engraving," as seen in polarized light. The fine striations on the primary and secondary bands may be noted also, while Fig. 10 shows this effect in greater detail.

b—In the portions of the crystal which, until now, were free of bands, another system developed made up of alternating lamellae about 10 microns thick and differing slightly in orientation. The general direction of the interfaces was still a (110) plane of the actual crystal, but it was no longer the same one as before, Fig. 11.

Examination of the slip lines on the surface of the polished specimens before the last rolling operation confirmed particularly clearly the existence of the bands and of gradual curvature in the connecting zones. Fig. 12 shows one of these first bands with the secondary bands. At a higher magnification the curvatures appear still more clearly and it will be noted on Fig. 13 that the connecting zone is wider on the upper front than on the other. The secondary bands also appear.

All these descriptions are naturally somewhat schematic. In reality, the initial crystal undergoes a change of orientation as a whole which varies slightly from one point to another and which cannot be explained by the geometry of deformation alone. Fig. 14 is a stereographic projection on a (100) plane of the poles of the rolling plane and

rolling direction after different degrees of cold working for a zone of the crystal judged to be typical of the average behavior.

5—Rolling Reduction 65 Pct: Successive polishing operations made the initial bands disappear. These were approaching nearer to the rolling plane. The complex systems are to be found close by but interpretation is still not possible.

In contrast, far away from these, the system already described, which possesses a (110) plane of the initial crystal as an interface, was still present.

Up to 65 pct reduction, it is striking that the rolled monocrystal was very far from being entirely affected by the bands described. Indeed, they only penetrated up to one fifth of the specimen thickness and from only one surface, in the case of the larger bands, while the finer systems penetrated from one surface only from one third to one half the thickness. This is evidently due to the very great heterogeneity of forces in rolling. These forces applied to the lattice vary through the thickness of the specimen and are very different at each rolling surface.

6—Rolling Reduction 208 Pct: Close to the previously formed large bands, interpretation remains impossible. There were at least two systems which could not be related to the orientation of the initial crystal with any certainty. On the whole of the opposite face, the face on which no system had been previously observed, there now appeared one made up of lamellae 15 microns thick. Interpretation was not possible however.

Far from the initial bands, the system already described was found again but it had not progressed

toward the interior. Thus both faces were now covered with fine bands and with several entangled systems. Between these two zones, at the center of the specimen, was a zone which, having undergone only rotation as a whole and simple slipping, was not fragmented.

Crystal B: This crystal was chosen to have an orientation close to that of crystal A, see Fig. 2.

Up to 5 pct reduction, nothing was noticed. After 13 pct reduction, bands appeared again with an interface corresponding to a (110) plane of the initial crystal, but this time making a large angle with the rolling plane, in contrast to the case of crystal A. The orientation difference was small but increased with increasing rolling reduction. After 20 pct reduction, a rotation of about 12° had occurred about the [111] axis contained by the (110) interface plane. The connecting zone was about 20 microns wide at this stage and the bands 70 microns thick. Analogy with the first-formed bands of crystal A is therefore very satisfactory. The presence of distinct bands mixed up with previously formed ones is worth noting. These are much more numerous on the other face of the specimen. This second system was more complex. Its interface, appearing on the large surface, was built up of straight portions, parallel to the trace of a (110) plane but connected by curved portions. On the other hand, the interface was linear on the side surface and still parallel to the same (110) plane. It therefore seems that the interfaces are (110) planes or ruled surfaces and

Fig. 11—Systems of bands in alternating lamellae in a portion of the crystal free of large bands. See Fig. 7. X75. Area reduced approximately 50 pct for reproduction.

show a certain analogy with cross slip. The width of the bands was 50 to 60 microns, the connecting zones were spread over about 20 microns, and rotation occurred around the same [111] axis as before, contained in the (110) interface plane (different from that of the system on the other face).

This crystal presented certain marked analogies with crystal A. The mechanism by which the bands formed was identical.

Crystal C: The orientation of crystal C is given in Fig. 2. After 5 pct reduction, nothing was observed and there was still nothing on the large faces after 15 pct reduction. However on the side surfaces of the crystal, a system of fine bands 20 microns thick was visible. These alternated regularly forming a layer approximately parallel to the rolling plane. This layer was made up of bands of differing orientation. The orientation of the portion of the crystal free of bands, was present also in the disturbed regions where it formed one element of the pattern. However, there was a slight rotation which

Fig. 12—Slip lines formed on the section of the crystal when the degree of reduction was increased from 25 pct to 45 pct. The primary and secondary deformation bands are revealed by the curvature of the slip lines and by relief on the metal surface. X75. Area reduced approximately 60 pct for reproduction.

made crystallographic identification of the interfaces very uncertain.

In the whole system, three principal orientations were established: one close to that of the surrounding crystal, and two others of slightly differing orientation.

In searching for orientation relationships between neighbors, these seem to be related by rotations of

Fig. 13—Portion of Fig. 12 at X600. Note the continuous curvature in the connecting zone and substructure of the band. Area reduced approximately 50 pct for reproduction.

about 5° to 10° around the axes $[112]$, $[110]$, and $[100]$. These axes cannot be determined with precision however. In like manner, it is not possible to see if the general direction of the interface between the bands themselves is a simple crystallographic plane of the original crystal.

The rotation around a $[112]$ axis has already been observed by Chen and Mathewson¹⁰ by X-ray examination on aluminum monocrystals cold-worked by extension. The interface of the deformation bands was a (110) plane as it is for the rolled crystals A and B described in this paper.

Crystal D: Crystal D was chosen to have a (111) plane almost parallel to the plane of rolling.

1—After 8 Pct Reduction: The etch-figures did not undergo any orientation change but they grouped together in wide zones of high density (20 to 250 microns). The interfaces of these zones appeared to be well defined and, in the plane of rolling, were parallel to the sides of the etch-figures (equilateral triangles almost).

On the rolled surface, thin oxide films and "engraving" revealed deformation bands once more. The orientation of these could not be deduced from angle measurement of the etch-figures. The interfaces were also confirmed.

On the side surfaces, no trace of deformation was

revealed by any of the micrographic methods.

2—After 15 Pct Reduction: The intensely attacked regions became more complex. They were to be found in the form of entangled bands formed by two crossing systems.

By measuring a large number of the etch-figures and plotting the orientations on a stereogram, it was found that they were grouped in two principal orientations. One was close to that of the original crystal and the other appeared to be related by a rotation about a common $[110]$ axis. In fact, the great complexity made orientation determination very uncertain.

Discussion and Summary

From the preceding experiments, it may be concluded that when a monocrystal is subjected to progressive rolling-reductions, not only is a general change of orientation produced, but also deformation bands become increasingly numerous and complicated. Such bands, at least those formed during progressive rolling, do not involve the whole thickness of the specimen at the beginning. In certain cases, they form either on only one face in contact with the rolls and then on the other; on both faces at the same time; or they may appear in the interior of the monocrystal. These peculiarities probably arise from variations in the resulting forces and from the orientation of these forces with respect to the induced lattice.

The first two specimens described were most suited

Fig. 14—Positions of the plane and direction of rolling after different degrees of reduction. Stereographic projection on a (100) plane. Solid circle, pole of the rolling plane. Open circle, pole of the rolling direction.

Fig. 15—Bending in crystal A. A—Idealized bending of a lattice oriented with a $[111]$ axis in the plane of rolling and perpendicular to the rolling direction. A (110) plane is thus parallel to the plane of rolling. B—Actual bending which occurred in the case of crystal A.

to precise analysis, as the bands formed initially were few in number, and were relatively large and well separated. In addition, the difference in orientation between bands and crystals was considerable. These bands are formed by progressive curvature of the lattice due to rotation around a $[111]$ axis (the start of the curvature is restricted to a (110) interface plane which contains this $[111]$ axis). The deformation band is thus contained between two parallel planes (110) of the original crystal. For the two specimens of closely similar orientation with respect to rolling, it is the same $[111]$ axis which functions as the axis of rotation. This axis is differentiated from others of the same index $[111]$ because it is that which is most nearly parallel to the rolling plane and perpendicular to the rolling direction. In other words, it corresponds to those $\{111\}$ planes most nearly perpendicular to the rolling plane and parallel to the direction of rolling. This will be easily appreciated since, under the mechanical conditions of rolling, such $\{111\}$ planes are literally blocked and prevented from undergoing normal slip.

There is here a fairly close analogy with the mechanism of kinking in hexagonal crystals which occurs when the active direction is parallel to the only slip plane possible. Fig. 15A shows the manner in which bending of the lattice is produced according to this mechanism. Fig. 15B shows the actual arrangement in the case of the first specimen. It is worth pointing out that bending occurs in the only way which permits a shortening of the $[110]$ axes, that is to say, a decrease in thickness of the specimen. In Chen and Mathewson's experiments,¹⁰ the glide direction was in the plane of the tension axis just as it is in the plane of the compression axis in our own experiments.

In the second specimen, bending is no longer given by the curvature of the $[110]$ axis which is the most nearly vertical, but instead by the two other axes almost equally inclined with respect to the rolling plane. Interpretation of the band formation appears more complicated if only the geometric process is considered.

Within the bands themselves, the same mechanism of orientation change in localized regions operates. The rotation occurs about the $[111]$ axis contained by the (110) interface plane of the new lattice. This $[111]$ axis is common to the initial crystal, and the primary and secondary bands. Therefore the orientation changes are simply additive.

In the first stages of deformation it appears clear that certain planes and axes play a somewhat special role which can be expressed in two ways: 1—Crystal-

lographically—it can be said that the $\{110\}$ planes are planes of high dislocation density, the dislocations being propagated on the $\{111\}$ planes in the directions $[110]$. 2—Mechanically—this amounts to recognizing the directions $[110]$ as having minimum elastic resistance to elongation or to shortening.

The formation of the present deformation bands is comparable from the point of view of crystallography with that observed by Cahn¹¹ and Honeycombe¹² in the tensile extension of aluminum single crystals.

Multiple and complex systems of deformation bands appear as deformation continues, or for certain initial crystal orientations. Only some of these systems have been defined as exactly as the bands already described. It seems they can only be distinguished from them by their more numerous and finer distribution, the rotation axis excepted.

For other systems of thin multiple-lamellae, when the deformation is over a certain limit, it is not possible to identify their positions even relative to one another, with any certainty. Their multiplicity must, without any doubt, finally define the crystallographic properties of rolling textures. It is striking to observe the formation of multiple, superposed patterns, each of them being formed by lamellae of alternating orientation. It is very evident that for texture studies, X-rays can produce only supplementary information, the interpretation of which would appear very difficult in the light of the complex phenomena which have been described for the simpler cases.

Statistical Grain Structure Studies: Plane Distribution Curves of Regular Polyhedrons

by F. C. Hull and W. J. Houk

To clarify interpretations of grain structures and to assist in calculations of spatial grain size distributions, plane distribution curves have been determined for random sections through four regular polyhedrons approximating the shapes of metal grains. The characteristics of the distribution curve for the average metal grain are predicted.

IT was realized early in the history of metallurgy that metals are polycrystalline aggregates and that the size and shape of crystals affects the properties of the material. Réaumur¹ in 1722 employed the microscope to examine the fractured surfaces of steel and of white and gray cast iron and suggested a polyhedral arrangement of the crystals. The first extensive investigation of the form of crystal grains was carried out by Desch.² He examined the disintegrated grains from a β brass sample and noted that the number of faces per grain ranged from eleven to twenty and that the number of edges per face varied from three to eight and the maximum occurred at five.

While it has been found practical to examine isolated grains only in exceptional cases, it is always possible to make a plane section through the metal and examine the shape of the grain sections on the plane of polish. Desch² tried to determine the relation between the form of a polyhedron and that of its plane sections for comparison with distribution curves of numbers of sides per grain section of actual metal samples. The polyhedrons investigated were the rhombic and pentagonal dodecahedrons and the orthic tetrakaidecahedron. However, the frequency distributions of the number of sides of plane intersections were not sufficiently characteristic to decide which polyhedron most closely approximated the average grain in a metal.

Determination of Statistical Shape of Grain in Space

Scheil³ was interested in the problem of calculating the distribution of grain sizes in space from the easily measured distribution of grain section sizes on the plane of polish. Assuming that the grains were spheres and using the plane distribution curve for a sphere shown in Fig. 1, he employed a successive subtraction method to calculate the spatial distribution.

In order to evaluate the accuracy of these calculations, Scheil and Wurst⁴ determined the actual distribution of grain sizes in space in their sample of ingot iron by polishing off successive layers and following every individual grain in a series of micrographs. From curves of mean radius of intersection

of a given grain vs thickness of metal removed in polishing, Scheil and Wurst attempted to derive the statistical shape of a grain in space. Their calculated plane distribution curve for this shape is compared with the distribution curve for a sphere in Fig. 1. A table of values based on this curve was prepared for calculating spatial distributions of grains. The calculated and measured spatial distributions of their sample then agreed much better than when a spherical shape had been assumed.

In the present paper, an attempt has been made to learn something about the average metal grain by studying in detail the effect of the shape of regular polyhedrons on the plane distribution of areas and shapes of areas produced by random sections through them. From the data presented below, it can be concluded that the plane distribution curve for the average metal grain differs in three fundamental respects from the curve derived by Scheil and Wurst.

Polyhedrons Selected for Study

The polyhedrons selected for the statistical study are illustrated in Fig. 2 and consisted of a cube, a figure formed by cutting off the corners of a cube at the midpoints of the original edges, a tetrakaidecahedron, and a pentagonal dodecahedron. The length of edge on any one figure is a constant. For the above models the edge lengths were 3.50, 4.00, 2.00, and 2.08 in., respectively.

A cube was selected for one of the polyhedrons because of its simple geometry, because it is a form that by repetition can completely fill space, and because it represents a convenient degree of departure from compactness beyond which the shape of

equiaxed metal grains would not be expected to extend. The "special polyhedron," with six square faces and eight triangular faces, represents an arbitrary step in the direction of greater compactness. It is not a space-filling polyhedron.

The tetrakaidecahedron of minimum area, which has eight six-sided faces with double curvature and six four-sided plane faces, is the only polyhedron that satisfies all surface-tension requirements. For ease in constructing the model and evaluating the areas of intersections, this shape has been approximated by the orthic tetrakaidecahedron. Although the form with plane faces and straight edges does not fulfill the surface-tension requirements, the difference in the figures, insofar as the plane distribution curve is concerned, is negligible.

The pentagonal dodecahedron is not in itself a space-filling figure, as is the tetrakaidecahedron. With its twelve five-sided faces, this figure approaches the characteristics of the average metal grain closer than does any other regular polyhedron. However, this comparison is only an approximation because a metal grain has variety in size, shape, and number of faces. By considering the characteristics

of all the polyhedrons, some generalizations can be drawn that are applicable to the average metal grain.

Experimental Procedure

Preliminary calculations and measurements of plane distribution curves of a cube and the "special polyhedron" were carried out by one of the authors at Carnegie Institute of Technology in 1940.⁶ The experimental procedure involved lowering wire models into water, using fifteen different orientations, and measuring the area of intersection as a function of depth of immersion. More recently at the Westinghouse Research Laboratories, the analysis was extended to the tetrakaidecahedron and the pentagonal dodecahedron and to a re-evaluation of the cube, using a more accurate and convenient procedure which was suggested by Roy L. Anderson. The technique is illustrated in Fig. 3.

A wire model of the polyhedron mounted on a rod was held in a tilting bench vise supported by an elevating table borrowed from a Rockwell hardness tester. Vertical displacements of the table and model were read on a dial gage. As the model was raised, it passed through a circular opening in a plywood panel. The top of the panel was parallel to the surface of the elevating table. The shapes and sizes of sections were obtained by sliding templates made of cardboard into contact with each face of the polyhedron intersected by the plane of the panel. The templates were temporarily held in place with masking tape. The panel was then transferred to a desk, a smooth-topped circular blank replaced in the opening, and the area of intersection evaluated with a planimeter.

As the model was raised, the shapes of the intersections were noted. Every time a corner passed the plane of the panel, the intersection polygon gained or lost a side. The elevation was then measured, and the number of sides was counted. From the point of first reaching the panel level, area measurements were made at 0.2-in. intervals up to and including an elevation corresponding to the center of the polyhedron. Because of the symmetry of the figure it was not necessary to go beyond the midpoint. A typical curve of area of intersection and number of sides of the intersection vs elevation, for the tetrakaidecahedron, is shown in Fig. 4.

The procedure used in selecting orientations of the sectioning plane with respect to the polyhedrons was as follows: The polyhedron, for example the cube, was assumed to lie in the center of a stereographic projection reference sphere with a face

Fig. 3—Position of pentagonal dodecahedron being adjusted with elevating screw.

Fig. 4—Area and shape of intersection vs elevation for tetrakaidecahedron of orientation No. 26.

parallel to the projection plane. All possible orientations of a plane with respect to the cube (identified by a normal to the plane passing through the center of the cube) can be represented by a point on the reference sphere and the corresponding point on the stereographic projection. However, because of the symmetry of the cube, it is only necessary to consider orientations lying within one of the twenty-four equivalent stereographic triangles defined by poles of the (001), (011), and $(\bar{1}11)$ planes. The orientations of the sectioning plane with respect to the cube are illustrated in the polar stereographic net plot in Fig. 5 and were selected to give as complete and representative sampling as possible with only twenty-six points. As an aid to distributing the orientations uniformly over the surface of the reference sphere, circles were drawn around each point with a diameter equivalent to a 5° solid angle. The distortion resulting from the method of plotting leads to a much smaller circle for the [001] direc-

Fig. 5—Polar stereographic plot of orientations of sectioning plane with respect to cube.

tion, for example, than at $[\bar{1}11]$. Angular relationships are listed in Table I for the cube and the other polyhedrons. θ represents angular inclination of the normal to the sectioning plane with respect to the [001] direction and ϕ represents angular rotation about [001]. If an orientation lies on an element of symmetry, it must be weighted as less than one in accordance with the number of equivalent stereographic triangles shared by the orientation. This consideration accounts for the weight factors listed in Table I.

Analysis of the Data

The data obtained by curves of the type illustrated in Fig. 4 have been analyzed to provide curves of frequency of occurrence of intersections with a given number of sides, distribution of areas resulting from intersections with certain numbers of sides, distribution curves of areas, and distribution curves of section diameters. Assume that a polyhedron is cut by a plane of a given orientation and that the area of intersection is A . A parallel plane displaced a distance Δx from the first will have

Fig. 6—Distribution of number of sides on plane sections of three polyhedrons.

an area of intersection of $A + \Delta A$. The probability of getting an intersection of area A to $A + \Delta A$ from the given orientation is proportional to Δx . If this probability is summed for all possible orientations and positions of the plane with respect to the polyhedron capable of producing such an area, a frequency distribution of areas is obtained. Orientations lying on an element of symmetry receive less weight, as has been explained.

The frequency function, $F(A)$, has the characteristic that the area under the curve between any two values of area is proportional to the number of intersections per unit area in that size range. In the present paper the "diameter" of an intersection has been defined as $D = \sqrt{A}$. Since it is frequently useful to express distribution functions in terms of diameters, the following relationship is defined:

$$F(A)\Delta A = F(D)\Delta D$$

Since

$$\Delta A = 2D\Delta D$$

then

$$F(D) = 2F(A)\sqrt{A}$$

Discussion of the Distribution Curves

The distributions of number of sides on intersections of the cube, tetraikaidecahedron, and pentagonal dodecahedron are shown in Fig. 6. These curves were obtained by summing the weighted values of Δx , irrespective of areas of the intersection, for each number of sides of the plane section. The cube has a maximum of four-sided sections, with no intersection having more than six sides. In spite of the considerable difference in shape between the other two polyhedrons, both exhibit a pronounced maximum at six sides per plane section, and show surprising similarity over the whole range of the frequency plot. The shapes of these curves are more reasonable than those obtained by Desch's more approximate sampling technique.² From the cube with only six faces to the other twelve and fourteen-faced figures, there is a shift to larger numbers of sides on the plane sections, as would be expected.

When the geometry of a polyhedron is considered, it is readily seen that the area of an intersection generally increases with the number of sides of the

section. It is difficult, however, to visualize the frequencies and ranges of areas possible for each number of sides of a section. A quantitative presentation of the distribution of areas for each shape of intersection possible is made for the cube, the tetraikaidecahedron, and the pentagonal dodecahedron in Figs. 7 to 9.

For the cube (Fig. 7), small three-sided intersections are very frequent, but the number decreases to zero at 10.4 sq in. Four-sided intersections are found from the smallest up to the largest area. The maximum in the distribution function at 12 to 13 sq in. results from the large number of positions of the sectioning plane that produce the same area when the plane is approximately parallel to a cube face. Five and six-sided intersections have reasonably normal frequency distributions of areas. The maximum area is the same as for the four-sided intersections, but the minimum and average areas increase with number of sides.

The tetraikaidecahedron curves in Fig. 8 exhibit similar trends but extended to intersections with up to ten sides. Although the minimum and average areas increase with the number of sides, the largest section possible has only eight sides. The double maximum in the frequency for six sides is comparable to the curve for four-sided intersections of a cube. It results from the shape and symmetry of the

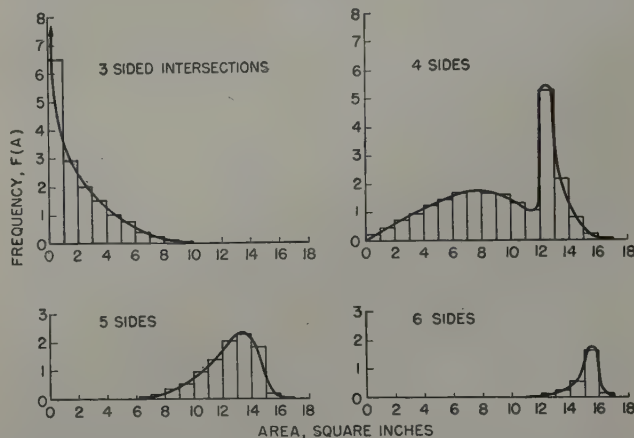

Fig. 7—Distribution of areas for 3, 4, 5 and 6-sided intersections of a random plane with a cube.

figure and thus has no particular significance for irregularly shaped polyhedrons.

The minimum, average, and maximum areas of the pentagonal dodecahedron (Fig. 9) increase with the number of sides of the section. Distribution curves for six and eight-sided intersections are slightly skewed as a result of a geometrical coincidence.

The curves for these three regular polyhedrons are useful in predicting the types of curves that might be obtained for the average metal grain. It is clear that the larger the number of faces on a grain, the larger will be the possible number of sides on an intersection. Since the faces on a metal grain are not necessarily parallel and are different sizes and have from three to about eight edges, there are fewer possibilities for the peculiarities in distribution that arise in regular polyhedrons. For the average grain, the minimum, average, and maximum area would increase more regularly with the number of sides of the intersection, and the frequency distribution of areas would be more normal. For polyhedrons of twelve to fourteen faces, the fre-

quency of occurrence of five, six, and seven-sided intersections would still be high, and intersections of ten or more sides would be exceedingly rare.

The plane distribution curves of areas, irrespective of the shapes of the intersections, are obtained by summing the above curves. For the four polyhedrons illustrated in Fig. 2, the distribution curves of areas are plotted in Figs. 10 to 13. All four curves are characterized by a rapid rise in frequency, $F(A)$, at small areas of intersection. Furthermore, each curve has a pronounced maximum in frequency at a value of $A/A_{\max.}$, somewhere between 0.7 and 0.9, with the frequency dropping to zero at the largest area possible.

For direct comparison with plane distribution curves of the sphere and Scheil's statistical grain shape (Fig. 1), these frequency curves, evaluated experimentally in terms of areas, have been converted by calculation to frequency distributions of section "diameters" using the relationship derived earlier in this paper. One strikingly similar feature of the four plane distribution curves of section diameters in Figs. 14 to 17 is that the frequency does not gradually drop to zero as D approaches zero. Such a behavior is theoretically correct for a sphere, but is not to be expected in the case of polyhedrons or grains with edges meeting at sharp corners. This can be demonstrated in the following way.

For polyhedrons having three straight edges meeting at every corner, the small intersections will be triangles except for a few unique orientations of the cutting plane. For a given orientation, the intersections at a series of elevations are similar triangles whose areas increase with the square of the eleva-

Fig. 8—Distribution of areas for 3 to 10-sided intersections of a random plane with a tetrakaidecahedron.

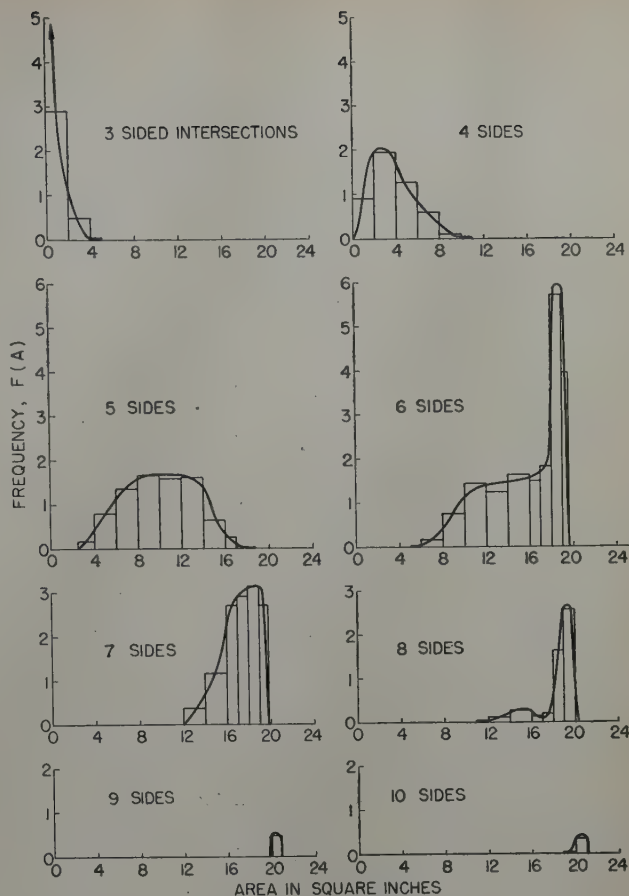

Fig. 9—Distribution of areas for 3 to 10-sided intersections of a random plane with a pentagonal dodecahedron.

tion and whose linear dimensions increase proportionally with distance,

$$D = k_1 x$$

The frequency of occurrence of areas with diameter D to $D + \Delta D$ from orientation 1 is proportional to Δx , that is $F_1(D) \sim \Delta x$ but

$$\Delta x = \Delta D / k_1$$

Therefore

$$F_1(D) \sim \Delta D / k_1$$

For equal increments of ΔD , $F_1(D)$ is a constant. The entire frequency curve at small values of D is obtained by summing such expressions for all orientations, and since the sum of a series of constants is still a constant, the $F(D)$ curve has a finite intercept and approximately zero slope at $D = 0$.

Distribution curves for the polyhedrons studied show a pronounced maximum in frequency at values of $D/D_{\max.}$, between 0.85 and 0.95, and again the frequency drops to zero at the largest diameter of section possible. The detailed shapes of the frequency curves over the whole range of section diameters reflect differences in the compactness of the polyhedrons and their degree of symmetry.

The plane distribution curve for a statistical metal grain must have the four characteristics outlined above:

$$F(D) = \text{finite at } D = 0$$

$$\frac{dF(D)}{dD} = 0, \text{ at } D = 0 \text{ and } D/D_{\max.} = < 1$$

$$F(D) = 0, \text{ at } D/D_{\max.} = 1$$

Fig. 10 — Plane distribution curve of areas for a cube.

Fig. 11 (left) — Plane distribution curve of areas for special polyhedron.

Fig. 12 (right) — Plane distribution curve of areas for tetrakaidecahedron.

However, it would be expected from the lack of symmetry in the average metal grain that the maximum in frequency would not be as high or as narrow as in the case of the regular polyhedrons and that it would occur at a smaller value of the ratio D/D_{max} . Since occasional small faces are possible on a metal grain, the frequency curve of the average grain would rise more rapidly in the range of small values of the diameter. Aside from these generalizations, little can be said quantitatively about the plane distribution curve of the average metal grain until experimental data are obtained on grains from disintegrated samples to serve to evaluate such a curve.

Characteristics of Polyhedrons

In order to compare characteristics of the polyhedrons on a uniform basis, the dimensions of each were selected so that all the models had the same volume. For simplicity, it was assumed that the number of grains per unit volume, N_v , was equal to

1. The second entry in Table II gives the surface area of each polyhedron. The sphere naturally has the minimum surface per unit volume, but this represents an unattainable minimum in so far as metal grains are concerned because stacked spheres by themselves cannot completely fill space. A cube might be considered as an extreme in the opposite direction according to Kaiser,⁶ excluding consideration of elongated or columnar grains. The three other more compact polyhedrons all have about the same surface per unit volume, indicating that the value is not too sensitive to actual shape for regular polyhedrons with twelve to fourteen faces. Since there is only about a 20 pct spread in areas between the sphere and the cube, it is reasonable to conclude that the surface area of actual grains can be approximated very closely by assuming them to be tetrakaidecahedrons, as was done by Rutherford, Aborn, and Bain.⁷

Fig. 13 — Plane distribution curve of areas for pentagonal dodecahedron.

Table II. Characteristics of Several Polyhedrons

	Cube	Special Polyhedron	Tetrakai-decahedron	Pentagonal Dodecahedron	Sphere
Volume	1	1	1	1	1

		1.52	1.32	1.32	1.24

Fig. 14 — Plane distribution curve of section diameters for cube.

Fig. 15 — Plane distribution curve of section diameters for special polyhedron.

The entries for radii of inscribed and circumscribed spheres give a measure of the extent to which the corners of the polyhedrons protrude. The radius r_i is obtained by averaging the maximum elevation for all orientations of the polyhedron, giving each position its proper weight. On the average, grains whose centers lie within a distance r_i on either side of a sectioning plane will produce intersections. For unit area on the plane, the number of such intersections, n , is equal to the number of grains lying in a volume of $2r_i \times 1 \times 1$, which is $2r_i N_v$. Since $N_v = 1$ by choice in the present instance, $n = 2r_i$.

One of the valuable uses of the distribution curves is that the average area of intersection, \bar{A} , produced by a given polyhedron can be calculated:

$$\bar{A} = \frac{\int_0^{A_{\max.}} F(A) A dA}{\int_0^{A_{\max.}} F(A) dA}$$

From the dimensions of a polyhedron, the maximum area of an intersection, $A_{\max.}$, may be calculated. Sauerwald⁸ and Gulliver⁹ have pointed out that the ratio $A_{\max.}/\bar{A}$ on the plane of polish of a metal sample is a measure of the uniformity of grain size in space. Formerly, there was no information on which to base an estimate of what this ratio should be for grains, except the value of 1.5 for spheres. For polyhedrons reasonably approaching actual grain shapes, it is seen in Table II that $A_{\max.}/\bar{A}$ should lie in the range 1.8 to 2.0. The more the ratio for a given sample exceeds this theoretical minimum (for a single size in space) the greater is the range of sizes in space.

The number of intersections per unit area, n , equals $1/\bar{A}$ and also $2r_i$. Values of these quantities are listed in the last two rows of Table II. By the two independent methods of evaluation, n agrees closer than 3 pct, serving as a check on the accuracy of the distribution curves.

Interpretation in Terms of ASTM Grain Size Numbers

It has been long recognized that even with a constant grain size in space there would be a distribution of section sizes on a plane of polish. This fact was first expressed in quantitative terms, assuming grains were all spheres of a single size, by the plane distribution curve in Fig. 1. Rutherford, Aborn, and Bain⁷ analyzed this curve in terms of ASTM grain size numbers in order to permit a clearer interpretation of its significance in terms readily understandable to the metallographer. In a similar manner, from the plane distribution curves in Figs. 14 to 17 and the known relation between grain section diameter and ASTM grain size numbers, the percentage of grain sections in different ASTM grain size groups has been determined for the various polyhedrons. The results for the polyhedrons, the sphere, and Scheil's statistical grain shape presented in Table III permit an evaluation of the extent of error introduced by the assumption that grains are spheres. As was expected, the latter assumption leads to predicting more large sections and fewer small ones than produced by polyhedrons approaching the shape of the average metal grain. The distribution curve for the cube obtained at Carnegie Institute of Technology resulting from only fifteen orientations leads to values in Table III that agree reasonably well with those based on the more accurately determined curve for the cube.

A person making a visual estimate of grain size is impressed not so much by the relative numbers of

Fig. 16 — Plane distribution curve of section diameters for tetraikadecahedron.

each grain size present as by the relative areas occupied by each. Using the plane distribution curves again, it is possible to calculate the percentage of the section area occupied by grains in certain ASTM grain size groups. The results for the various polyhedrons also appear in Table III. Even with the extreme range of shapes from a cube to a sphere, the area occupied by the grains covering two ASTM grain size groups N and $N+1$ is between 94 and 97 pct of the total cross section. The large proportion of small grain section sizes usually seen on polished metallographic specimens can thus only be accounted for by a distribution of grain volumes in space. Actually, in all cases in which spatial distributions have been determined, a considerable spread about a mean size has been found.^{4, 20}

Conclusions

1—The average and maximum number of sides on a plane section of a polyhedron increase with the number of faces on the polyhedron.

2—The distribution of plane section shapes of a polyhedron depends primarily on the number of faces and is not much affected by the shapes of the faces on the polyhedron.

3—With minor exceptions, the minimum, average, and maximum areas of intersections with a given polyhedron increase with the number of sides on the intersection.

4—Experimentally and theoretically, it has been shown for polyhedrons that the distribution of section diameters is a constant at small values of the diameter.

5—All four of the polyhedrons studied have a pronounced maximum in the plane distribution curve at less than the maximum diameter, and the frequency at the largest section possible is zero.

6—The plane distribution curve for an average metal grain would exhibit the same general characteristics found for the regular polyhedrons, except that the maximum in the frequency curve would be much broader because of the lack of symmetry in the grain shape.

7—If a material has a completely uniform equiaxed grain size in space, then on plane sections, 94 to 97 pct of the area will be occupied by grain sections covering only two ASTM grain size groups N and $N+1$, regardless of the spatial shape of the grains.

Operations at New Cornelia Copper Smelter Of Phelps Dodge Corporation

by James W. Byrkit

Design features and operating methods at the new Ajo smelter are described in detail. Successful operation of a novel method of handling and charging wet concentrates to a deep bath type reverberatory furnace contribute to the daily production of 200 tons of anodes with good results from the standpoint of both metallurgy and economy.

THE New Cornelia Branch of the Phelps Dodge Corp. is located at Ajo, Ariz. Large scale mining operations were started at Ajo in 1917, when a 5000 ton leaching plant was put in service to treat the copper carbonate ore that overlaid the sulphide orebody. In 1924 a 5000 ton flotation plant was built to treat the sulphide ore and the leaching operation was abandoned a few years later. Changes in practice and additions to plant facilities have resulted in a gradual increase in the milling rate which now approaches 30,000 tons daily.

Prior to the erection of the Ajo smelter, flotation concentrate was shipped by rail to Douglas, Ariz., where it was treated in the Phelps Dodge smelter. Construction of a one reverberatory furnace smelter to produce an average of about 200 tons per day of copper anodes at Ajo was started early in 1949. Initial heating of the reverberatory furnace was begun on June 21, 1950. Charging the furnace was started on July 8, and the first anodes were cast on July 14. Neither the anode furnace nor the reverberatory furnace has cooled since the initial firing. Fig. 1 is a photograph of the new smelter.

Built primarily to eliminate the 300 mile haul of concentrate to the Douglas plant, the new smelter was designed to treat the Ajo concentrate, with a minimum of capital investment. A novel, and relatively simple, method of concentrate handling and furnace charging made unnecessary the installation and operation of expensive storage facilities and reclaiming equipment, and obviated the necessity of holding in storage large quantities of copper-bearing materials. (Patents are pending in the United States and abroad on the Ajo process.) In the selection and arrangement of equipment, consideration was given to the full utilization of all smelting facilities, reducing the amount of idle equipment to a minimum. The layout of the smelter is shown in Fig. 2. The

J. W. BYRKIT, Member AIME, is Smelter Superintendent, New Cornelia Branch, Phelps Dodge Corp., Ajo, Ariz.

Discussion on this paper, TP 3515D, may be sent, 2 copies, to AIME by July 1, 1953. Manuscript, Nov. 3, 1952. Los Angeles Meeting, February 1953.

Fig. 1—The new copper smelter, designed to treat the Ajo concentrates, eliminated the shipping of flotation concentrates to the Phelps Dodge Smelter at Douglas, Ariz.

important problem of internal transportation was minimized by arranging the reverberatory furnace, converters, and anode furnace in a compact group and providing storage bins inside the smelter building, within reach of overhead cranes, for fluxing materials and other supplies needed in the daily operation. This can be seen in the sectional view of the smelter given in Fig. 3. Incorporated in the design were many innovations in smelting equipment intended to facilitate operations and effect economies in maintenance expense and manpower requirements. Table I gives operating data of the entire plant.

Metallurgy

The metallurgical practice at Ajo is based essentially upon the use of a single, deep bath reverberatory furnace for smelting wet concentrate, without concentrate storage facilities. The large reservoir of slag and matte maintained in the furnace serves to equalize, to some extent, the day to day variations in the nature and grade of concentrate and permits

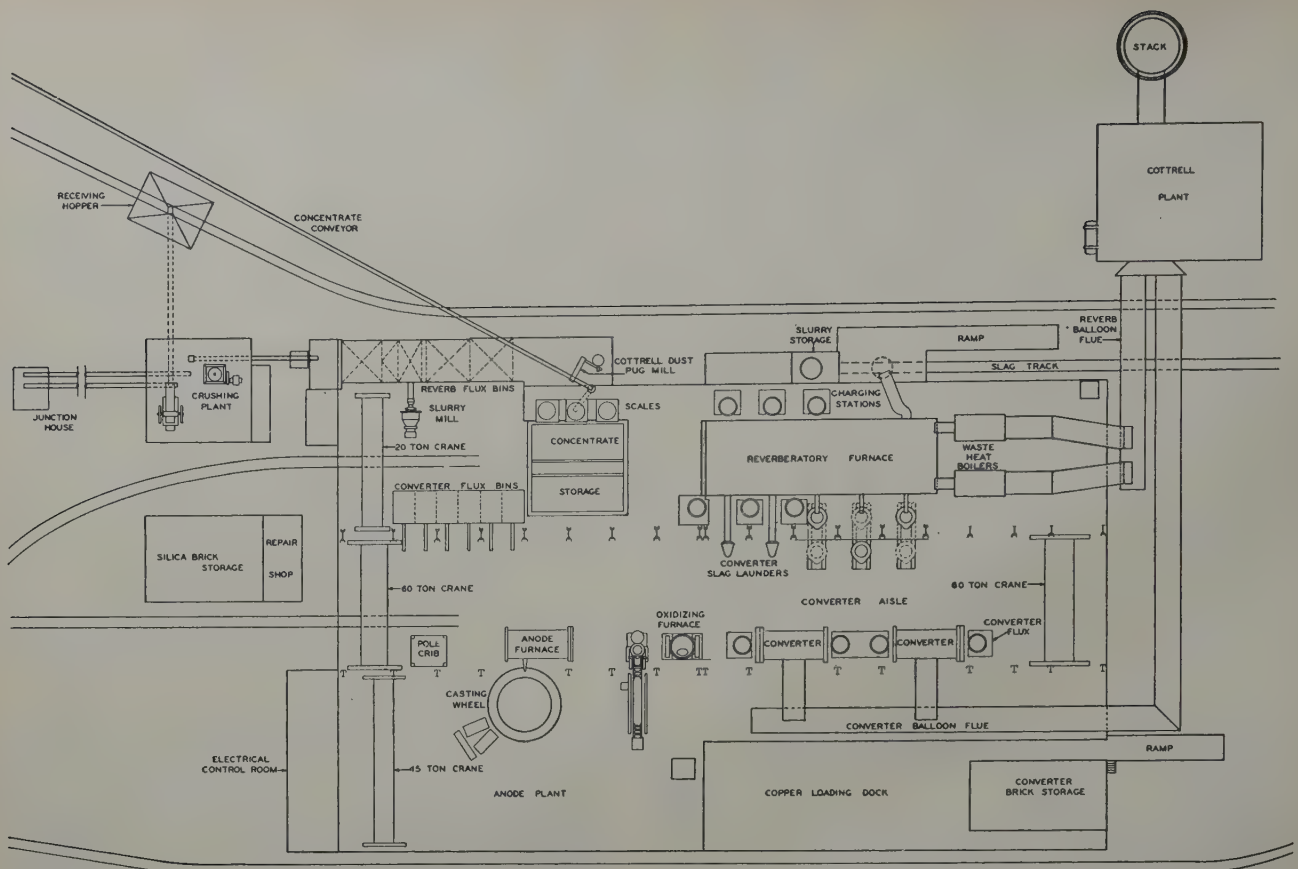

Fig. 2—Arrangement of equipment can be seen in this layout drawing of the smelter. The design permits full utilization of all smelting facilities, and the amount of idle equipment was kept to a minimum.

utilization of converting and refining facilities to the best advantage. The smelter flowsheet is presented in Fig. 4.

Concentrate is taken from flotation plant filters and transported to the smelter on a conveyor belt. Fine crushed limestone is added to the concentrate on the conveyor at a predetermined rate. Ordinarily no other fluxing material is used on the reverberatory furnace charge, which averages 95 pct concentrate. All siliceous fluxing material is charged to converters. The bulk of converter flux is tailing from the old leaching operation. This tailing is about $\frac{1}{3}$

in. in size and contains approximately 67 pct silica and 14 pct alumina. Barren quartz from a local quarry is crushed and blended with tailing to maintain a silica-alumina ratio of about 6 to 1. Custom shipments of siliceous ore constitute a minor portion of converter flux. All converter reverts are resmelted directly in converters.

Copper in the Ajo concentrate is present mainly as chalcopryite, with some bornite and occasional small amounts of chalcocite and native copper. The grade of concentrate varies from day to day, over a considerable range, with accompanying changes in

Fig. 3—This sectional view of the smelter shows the positioning of service equipment intended to facilitate internal transportation and operations. 1—Railroad flat car to refinery. 2—Fork lift truck for loading anodes. 3—Anode handling crane, one, 15 ton. 4—Balloon flue, converter. 5—Jug damper. 6—Converters, two. 7—Converter cranes, two, 60 ton. 8—Converter slag return launder. 9—Matte ladles. 10—Reverberatory furnace. 11—Concentrate "can." 12—Concentrate feeder belt. 13—Concentrate slinger. 14—Reverberatory cranes, two, 20 ton. 15—Slag pots.

iron and insoluble material content, depending upon the grade and nature of the mill feed. Matte grade varies with the copper content of the concentrate, ranging from 25 to 35 pct, averaging about 30 pct. Copper content of matte is usually 7.0 to 8.0 units higher than that of concentrate. Slags are fairly uniform in character and composition, copper content varying with matte grade and to some extent influenced by iron carried out in slag.

In the absence of intermediate storage, concentrate is smelted before analyses are available but lack of analyses before charging to the furnace has not been a handicap. Minor adjustments in converter fluxing are made on the basis of analyses of concentrate and final slag for the previous day. When visual appearance of the bath indicates the need, small additions of limestone or silica are made directly to the furnace. Charging of all siliceous flux to converters causes the formation of high-silica slags, but this practice has not perceptibly affected converter linings and has reduced the amount of magnetite returned to the furnace. Furthermore, smelting in converters of practically all silica flux used results in increased furnace capacity for concentrates, which at Ajo is an important factor.

Crushing Plant and Flux Storage

The smelter crushing plant was designed to prepare fluxing materials for converters and reverberatory furnace and to crush reverts and other materials used in the smelter operation. Coarse materials, such as barren quartz and custom ores, are received in either side or bottom dump railroad cars and are dumped into a 75-ton capacity bottom discharge concrete receiving bin. Materials are fed from the bin by pan feeder and belt conveyor into a 36x48 in. jaw crusher, the 3-in. product of which is conveyed to a 4x8 ft mechanically vibrated screen. The screen oversize falls into a 4 ft standard cone crusher set at about $\frac{1}{2}$ in. and remains in closed circuit until reduced to screen undersize. The screen undersize is transported by conveyor and bucket elevator to storage bins.

The leached tailing siliceous flux is loaded by shovel from the dump, which is about one mile from the smelter, into railroad cars and is passed through the plant without crushing. The desired blending of converter flux is accomplished by adding crushed barren quartz in the correct proportion. Limestone, received from an outside source as screened product, likewise requires no crushing. An auxiliary screen is provided inside the smelter building, over which barren quartz is passed, the oversize being used for converter flux, while the 6-mesh undersize is stored for use as furnace patching material.

Storage bins for both reverberatory and converter fluxes are so located in the smelter building that materials may be withdrawn through chutes into

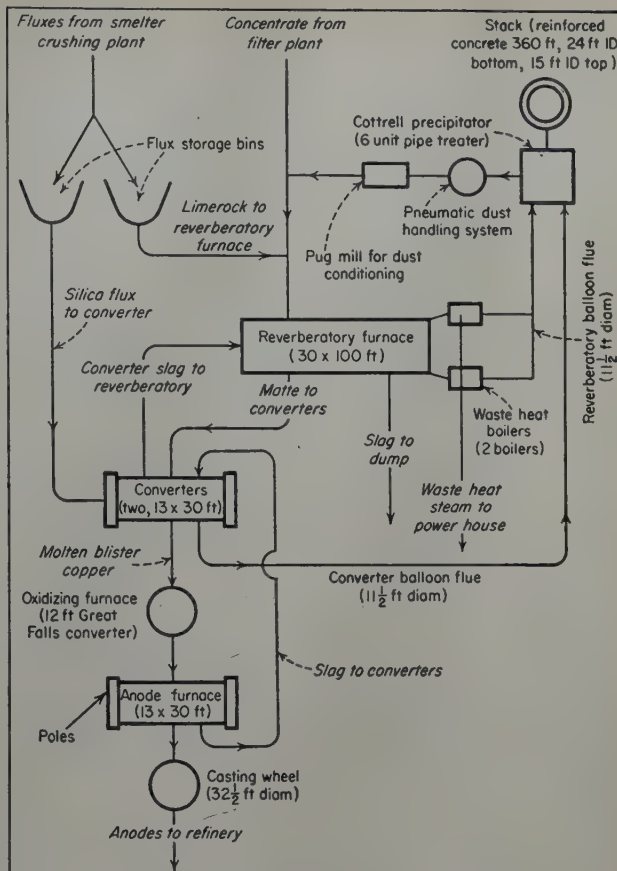

Fig. 4—The processing of the concentrate from the filter plant is diagrammed in the smelter flowsheet. The only fluxing material added to the reverberatory charge is limestone; all siliceous flux is charged to converters.

boats or containers for handling with overhead cranes.

Reverberatory Furnace

Design and Construction: The design and construction of the reverberatory furnace embodies several unusual features. The furnace, 100 ft long and 30 ft wide inside the brick walls, is mounted on a heavily reinforced monolithic concrete foundation which rests on a slab of concrete 5 ft thick. The walls of the foundation are $4\frac{1}{2}$ ft thick, with footings $8\frac{1}{2}$ ft wide that extend 2 ft below plant floor level. The top of the foundation is 11 ft above floor level. The foundation, as well as the furnace itself, is isolated on all sides, thereby avoiding transmission of expansion forces to the smelter structure that surrounds it.

The construction of a 10 ft subbase for the furnace hearth was accomplished by tamping in 3-in. layers of crushed diorite rock from the open pit, mixed with 20 pct mill tailings to fill voids. Above the subbase a $4\frac{1}{2}$ ft layer of granular magnetite, a product removed from the tailing of a New Mexico copper concentrator by magnetic separation, was tamped to dense compaction, followed by an 8 in. layer of material composed of 90 pct crushed magnetite slag and 10 pct granular magnetite. A 4 in. veneer of fire clay brick was laid on a corbel inside the foundation wall, for protection of the upper 30 in. of concrete against furnace heat.

The details of sidewall and furnace arch brick work are shown in Fig. 5. The basic crucible was tamped in 10-ft sections, using a mixture of granular periclase with minor amounts of ground periclase

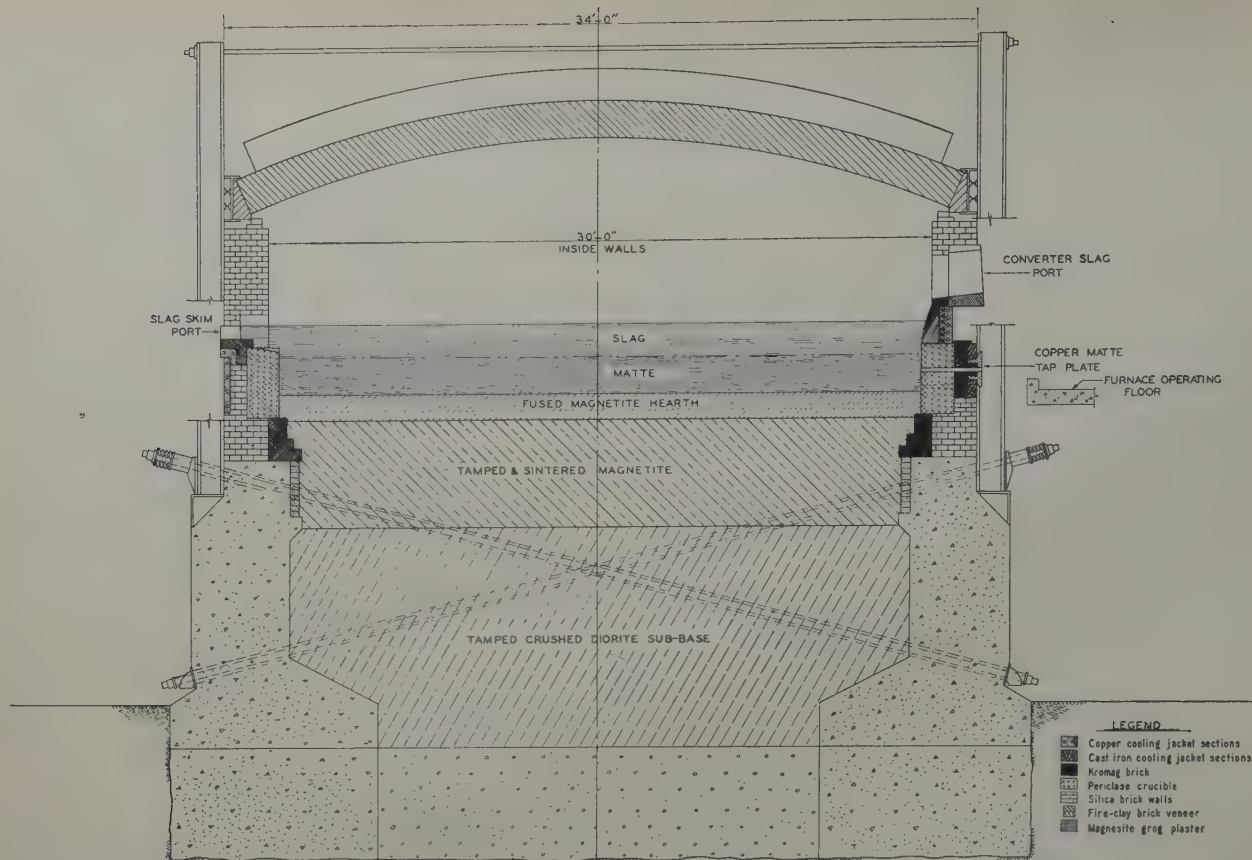

Fig. 5—Sidewall and furnace arch brickwork details, as well as the novel method of buckstay retention, are shown in this composite cross section of the reverberatory furnace. Furnace binding is of unusually heavy construction.

and fire clay, wetted with a controlled amount of sulphuric acid. Immediately above the crucible a row of copper water jackets, 20 in. high, replaces silica brick in the sidewalls extending as far as the skimming bay on one side and through the last matte tap hole on the tapping side. The 20-in. silica brick sprung arch has a span of $31\frac{1}{2}$ ft between skew-backs. The 15-in. ribs, spaced alternately 4 and 6 ft apart, permit installation of a relieving arch through two-thirds of the furnace length, if needed. Above the verb arch, uptake walls are of silica tile sectionally supported construction, and the suspended uptake arch is silica tile.

Furnace binding is of unusually heavy construction. Lateral buckstays are heavy H-beams, resting on an offset in the concrete foundation at the bottom and joined at the top to the opposite buckstay with a $2\frac{1}{4}$ in. square tie rod, threaded on both ends. Bottom thrust is taken by a heavy channel and angle box beam, running the length of the furnace, which is retained by spring loaded 2-in. tie rods extending diagonally through the furnace subbase to the bottom of the concrete foundation on the opposite side. This novel and effective method of buckstay retention is shown in Fig. 5. End binding is retained by heavy buckstays at each corner, which are tied at the bottom by $3\frac{1}{2}$ -in. rods anchored in the concrete foundation and at the top by $3\frac{1}{2}$ -in. tie rods running the length of the furnace, all of which are heavily spring loaded.

The magnetite bottom was fused in with an oil fire by regulating the admission of secondary air along the furnace walls and increasing the fuel until the entire surface had become liquid. Additional magnetite tailing was then charged through the sidewalls until a liquid pool had been formed, the surface of

which was at the desired final bottom level, about 11 in. below the center line of the matte tap holes. Firing was reduced and the magnetite bottom was allowed to solidify. At this point, molten converter slag, prepared by melting and converting concentrate in converters, was charged through converter slag launders and spread over the chilled bottom. Charging of concentrate was started at once.

Reverberatory Operations: Concentrate is received continuously during operating periods from the mill filter plant over a 24-in. conveyor belt, to which a predetermined amount of crushed limestone is added. Mixed concentrate and limestone are discharged into containers, called cans, resting on a platform scale by means of which the can and contents are weighed and the weights tape recorded. The can resembles a concrete bucket, with heavy lifting bails and sloping inner walls, at the bottom of which are double, air-operated arc gates. The capacity of a can is approximately 10 tons of charge, as-received. When the can has been filled, it is removed from the scale platform by a 20-ton overhead crane, and either set aside until needed, or transported at once to one of the six charging stations. When the charge can is in place over the charging station the bottom gates are opened and the charge fills the small hopper immediately below. A 1200-ton surge bin inside the smelter building is used to equalize mill production against smelter consumption. Concentrate delivered to this surge storage is reclaimed as needed with clamshell and overhead crane.

When the operator is ready to charge the furnace, he raises the door covering the charge port in the furnace sidewall and starts the short feeder conveyor under the charge hopper. Concentrate from the feeder falls into the feed hopper of the charging machine,

locally called the slinger. This machine is a short, high-speed portable belt conveyor pivoted on a vertical shaft that permits lateral swinging. The concentrate falls through the feed hopper onto the rapidly moving belt and, as it moves over the head pulley, is discharged into the furnace. This is illustrated in Fig. 6. The trajectory of the concentrate stream may be varied by elevating or depressing the head pulley, by means of an adjusting device, or by regulating the speed of the belt which is driven by a variable speed dc motor. The average charging rate is about 1 ton per min and the usual charge is 2 to 4 tons. Selection of charging station and timing of the charging period is largely a matter of judgment on the part of the operator, who attempts to keep the surface of the bath covered with a thin layer of unsmelted material. When visual appearance of the bath indicates the necessity, either limestone or silica fluxing material is charged to the furnace directly from cans used for that purpose. As the result of this method of charging small amounts of wet concentrate at frequent intervals, explosions caused by contact of wet charge with molten matte are completely avoided.

The normal liquid bath depth is about 42 in., with 24 to 28 in. of matte. Matte is tapped as required by converters into 175 cu ft ladles resting on electric motored trucks that are energized through the rails with 32 v dc. During the tapping period matte ladles are enclosed in cubicles located under the tap holes below the furnace operating floor which are provided with air-operated hinged doors. Two exhaust fans, one connected to the cubicle and the other to an enclosure around and above the matte launder, effectively remove all fumes from the tapping area, venting the gas to atmosphere outside the smelter building. Matte fall amounts to about 83 pct of concentrates charged.

Slag is skimmed through the furnace sidewall near the verb arch and is laundered into 225 cu ft pots. Fig. 7, a view of the reverberatory from the skimming end, shows the closing of the skimming hole. The usual practice is to skim a train load, consisting of three pots, in succession. Slag is hauled to the dump, about one half mile distant, with 25-ton diesel-electric locomotives. The slag dump is graded with bulldozers and new alignment is made with track shifters. Slag fall amounts to about 75 pct of concentrates smelted.

Fig. 6—Concentrate, in 2 to 4 ton charges, falls through a hopper onto a rapidly moving belt and is discharged into the reverb at a rate of about 1 ton per min. The operator regulates charging times and aims at keeping the surface of the bath covered with a thin layer of unsmelted material.

Converter slag is returned to the furnace through duplicate launders in the sidewall near the firing end. Slag inlet ports are formed by heavy, cast copper water jackets set in the brick furnace wall and are equipped with air-operated cast steel gates.

The reverberatory furnace is fired with natural gas. The original installation consisted of multiple jet burners, which functioned well except when a high firing rate was necessary. They were replaced with high pressure, locally made, barrel-type burners. Seven of the barrel-type burners spaced across the burner wall normally burn 185,000 cu ft per hr with good combustion. A view of the furnace from the burner end is shown in Fig. 8. Natural gas is received from New Mexico fields at 300 psi at the plant and

Fig. 7—After slag is skimmed through the furnace sidewall near the verb arch, the skimming hole is closed. Usually three 225 cu ft pots, a train load, are skimmed in succession.

Fig. 8—Seven barrel type burners, firing 185,000 cu ft of natural gas per hr, can be seen in this view of the reverberatory furnace. Standby oil burning equipment is available for emergencies.

is reduced to 42 psi at the burners. The gas contains about 1100 Btu per cu ft. Standby oil burning equipment is provided for use during periods when the natural gas supply is interrupted. Low pressure oil burners are constructed to fit inside the barrel-type gas burners. Firing can be changed from gas to fuel oil in about 20 min. Furnace combustion is checked frequently by Orsat analysis and a recently installed continuous oxygen analyzer indicates the oxygen content of furnace gases at all times. Effective use of the oxygen analyzer was made possible by the development of a successful method of sampling and cleaning furnace combustion gases by Leonard Klein, research metallurgist. Furnace draft is controlled automatically through dampers in back of each waste heat boiler. An automatically operated butterfly damper was installed in the converter balloon flue to regulate distribution of draft between converter and reverberatory operations. A curtain damper across the furnace at a distance of 10 ft from the verb arch, extends from the furnace roof to about 36 in. above the normal surface of the bath. The damper is constructed of 16 water-cooled panels joined together and covered with silica slurry. The damper serves to stabilize furnace draft, checks flow of dust into boilers, and tends to box in furnace heat.

Furnace sidewalls and arch are maintained by patching with silica slurry, a method developed at Phelps Dodge Corp.'s United Verde branch. Silica is ground and slurried to 65 pct density in a modified Hardinge ball mill and the mill discharge is conveyed through a high pressure blow tank and piping system to an agitator-storage tank located above the furnace operating floor. During patching operations slurry is withdrawn from storage tank into 10 cu ft pressure tanks, to which compressed air is applied, forcing the slurry through hose and pipeline to a nozzle suitable for spraying arch or sidewall. Meas-

urements of arch thickness made twice weekly through 11 measuring holes furnish information as to location in need of patching.

Reverberatory furnace operating data are shown in Tables II and III.

Converters

The general arrangement of the converter aisle is shown in Fig. 2, and a view of the converter aisle is given in Fig. 9. The aisle is 396½ ft long and 63 ft wide. Two cranes, each equipped with a 60-ton main hoist and two 20-ton auxiliary hoists, have a span of 60 ft with crane rails 55 ft above the floor of the aisle. Main hoist dc motors are 135 hp and auxiliary hoist motors are 75 hp. All hoist drives are equipped with two magnetic brakes, one on the armature shaft extension and one on the motor pinion shaft extension. All hoisting ropes are 1 in. preformed plow-steel, with independent wire rope center construction. Crane repair platforms are provided at each end of the aisle, above which are mounted 5-ton repair cranes.

Two 13x30 ft Peirce-Smith converters were moved from the Clarkdale smelter to Ajo over Arizona

Table IV. Converter Data (Dry Ton Basis)

highways by motor truck. These converters are spaced on 60-ft centers and are opposite the reverberatory matte tapping area. The converter shells are 1¼-in. plate, welded in 10-ft sections. Welded joints are reinforced with heavy butt straps welded to the shell on both sides. The 1-in. end plates are each stiffened with four I-beams and are retained in place with bolts and springs. Riding rings are mounted at the ends, clear of the tuyere section, and are riveted to the shell. Details of brick lining are shown in Fig. 10. Full insulation of converter shell and ends is believed to result in the retention of sufficient heat to resmelt all reverts and relatively large amounts of siliceous material in converters.

Converters are driven by 75-hp ac motors, direct connected to speed reducers and intermediate gears with a heavy pinion engaging a large gear bolted to one of the riding rings. Drive motors are equipped

with magnetic brakes and are controlled from the operating platform.

Each converter is equipped with 52 ball valve tuyeres, with 2-in. pipes rolled into the seat. The middle 16 tuyere pipes are reduced in diameter by seating a 1½-in. pipe inside the 2-in. tuyere pipe. Converter air is supplied by two 30,000 cu ft steam-driven turboblowers, located in the plant power house. Air is delivered at converters at a normal pressure of 13 psi, which may be varied by a system of controls on the converter operating platform. A warning signal is sounded when pressure drops below normal, giving the operator time to turn the converter out of stack if it is blowing. Air volume to converter will average about 25,000 cu ft per min with 30,000 cu ft per min maximum. Main blast valve is pneumatically operated and is controlled from the skimming platform. Air volume is indicated by a flow meter near the punchers platform and is recorded continuously on a meter in the converter office. Blowing time for each converter is recorded by a timing device in the office.

Converter hoods are of welded steel with cast iron liners. A sliding apron, covering the hood while the converter is blowing, is operated through an air cylinder and heavy wire ropes. A cast steel bell damper in each converter uptake just ahead of the balloon flue is raised and lowered by a motor-driven wire rope hoist. Adjustable punchers platforms are raised and lowered with a hydraulic lift. Punchers platforms and operators platforms for both converters are connected by hand-railed walkways.

Tuyere blocks are 18 in., four piece, hard-burned chrome-magnesite. Tuyere line campaigns will average about five months, finishing 12,000 to 15,000 tons of copper per set. When tuyere repair is made, brick immediately above and below tuyere line is renewed and brick is replaced in arches around the mouth, in the ends, and in the converter bottom when necessary. Steel work around the mouth is overhauled during repair periods and necessary repairs are made to silica feeders, stack, and tuyeres. Cast steel pour-

Fig. 9—Two 13x30 ft Peirce-Smith converters, finishing four charges of blister copper daily, are located in the converter aisle.

ing lips are covered with several layers of hard facing and usually last through two or three campaigns.

Normally, converters are charged with four 15-ton ladles of matte which is fluxed, blown, and skimmed, and sufficient additional matte is added to make up a charge of approximately 50 tons of blister copper. Four charges of blister copper are finished daily. Both converters are operated on the day shift and one converter only is blown on the afternoon and night shifts. Converter operating data are given in Tables IV and V.

Mixed converter flux is drawn from storage bins into cans similar to those used for handling reverberatory charge. The cans are transported by overhead crane to a platform above the converters where a charging station is located at either end of each

Fig. 10—Sufficient heat is retained by the full insulation of converter shell and ends, as shown in the detailed drawing of the brick lining, to resmelt all reverts.

Fig. 11—Blister copper is overblown in this oxidizing and holding vessel, a remodeled 12 ft Great Falls converter. Blowing copper high in this vessel, it is believed, results in longer brick life in the large converters.

converter. The flux flows through the can bottom discharge gates into a hopper which feeds Garr guns at each end of the converter. Additional storage bins make available fluxing materials with high silica content when needed. This method of handling converter flux has been entirely satisfactory and affords considerable flexibility in regulating this phase of the operation.

Converter aisle cleanup is accomplished to a large extent with a small bulldozer. The bulldozer operator cleans the aisle itself and the area under the converters before the start of the day shift, pushing the accumulated slop and spill into a pile at one end of the aisle. Ladle shells are loosened on a copper bumping block, dumped on the revert pile, and broken up with a drop ball. The entire accumulation is loaded into 10-ton boats by crane-operated clam-shell and charged to converters as needed. Dust from converter hoppers and from the converter balloon flue is drawn into a dump truck, dumped into a large boat, and charged to converters as operating conditions permit.

Oxidizing Furnace

A departure from conventional converter practice was made at Ajo, sometime after the smelter was started, by overblowing blister copper in a separate oxidizing and holding vessel. An old 12-ft Great Falls converter was slightly remodeled and installed for this purpose, equipped with a close fitting swinging hood and a stack vented to atmosphere, as shown in Fig. 11. The converter is lined with 9-in. chrome-magnesite brick and all but four of the sixteen 2-in. tuyeres are blocked off. The opening in the converter cap was reduced in size and, to make a closer fit with the hood, the normal position of the cap on the shell was reversed. An opening was made on one side of the cap through which a gas burner is inserted for heating the vessel and the copper charge.

When a copper charge is blown to light blister in one of the Peirce-Smith converters, the final slag is dammed off with cold reverts to permit the copper to be withdrawn clean into ladles and transferred to the oxidizing furnace. The charge is blown with converter air at about 13 psi under a fairly heavy gas fire. Complete sulphur elimination in a 50-ton charge is reached in about 30 min. No slag is formed in the oxidizing operation and the overblown copper carries an average of about 5 pct cuprous oxide. Further blowing in the anode furnace is not necessary.

It is believed that blowing copper high in a separate vessel results in longer brick life in the large converters, as it generally has been felt that conditions reached during the overblowing period were destructive to converter lining. The elimination of oxide slag in converter operation is a distinct advantage, as this material is dangerous to handle and slows down the operation while being skimmed and returned to converters. When needed as such, the vessel also may be used as a holding furnace, thereby permitting greater flexibility in the operation of closely designed converting and refining equipment.

Anode Plant

The anode plant is located in and adjacent to the converter aisle, with the single anode furnace in line with the converters. Design and construction of equipment used in both the refining and the casting operations included many innovations which have contributed largely to the effective performance and economical operation of the anode plant. Anode operating data are given in Table VI.

The anode furnace, shown in Fig. 12, is 30 ft long and 13 ft diam. The shell is 1½-in. plate, welded construction. The heads are dished ¾-in. plate with a heavily reinforced ring around the circumference 11 in. wide, making a slip fit inside the shell. The heads are fastened to the riding rings with eight spring-mounted bolts to accommodate expansion. A 4-ft round opening in the shell near one end serves as a charging port for copper and as an outlet for combustion gas; the copper pouring spout is located about 90° below the charging port near the opposite end of the furnace. Unlike most rotating anode furnaces, which have a common opening for poling and release of combustion gas, the poling door of the Ajo furnace is in one end, about 3½ ft above the center line of the furnace. The 30-in. opening is provided with a heavy steel ring bolted to the head, for the protection of brick lining during the poling operation. A hinged door is closed except during the time the furnace is being poled. Small ports in either end of the furnace serve for blowing with high pressure air when necessary, or for gas burners. The anode furnace drive is similar to converter drives, except that direct current is used.

The anode furnace is equipped with a swinging hood that covers the charge opening during the poling operation and is elevated when copper is

Table VI. Anode Copper Data

1951	99.75	0.01	0.129	64.3	0.856
1952 (6 mos.)	99.69	0.01	0.130	73.0	1.179

charged. The hood is connected to a steel stack which vents combustion gas to atmosphere through the roof of the building. The furnace is lined with chrome-magnesite brick with a 2½-in. layer of insulating material between the brick lining and the steel shell and ends. Retention of heat in the anode vessel by complete insulation results in better fuel economy as well as improved working conditions on the furnace operating floor.

As sulphur is completely eliminated from the copper charge during the blow in the oxidizing furnace, blowing in the anode furnace is limited to cleaning up the charge and skimming off a minor amount of slag just before the charge is poled.

Oak poles are unloaded from cars into a pole crib at the poling end of the furnace. Poles are raised to the operating floor with an air-operated derrick as needed and are manipulated in the furnace with a small air hoist. A heavy concrete pier immediately below the poling door is provided with rings holding a heavy chain which passes over the pole and takes the strain exerted by the hoist, thereby protecting the poling door and brick lining from damage during the poling operation.

The 700 lb anodes are cast on a 22-mold gear and pinion driven wheel. Copper from the furnace pouring spout is received in a hydraulically operated spoon and poured from it into molds at a normal rate of about 40 tons per hr, as can be seen in Fig. 13. The two dc motors driving the casting wheel are controlled on the Ward-Leonard principle, receiving power from a special dc generator. The armatures of the two 115-v motors are connected in series across the generator terminals.

Control of the casting wheel is semiautomatic. Started by push button, the wheel stops automatically when the next mold is in position under the spoon. The start of motion and acceleration is smooth enough that the wheel can be moved immediately when the mold is filled and cooling of liquid copper with an air blast is not necessary. Cooling water is applied through a series of sprays starting after the surface of an anode has chilled. Lifting pins to raise the top of the anode from the mold are actuated by a lever and roller arrangement that moves over an inclined track under the wheel. Anodes are lifted from molds by pneumatically operated tongs and dropped into one of two bosh tanks, each of which holds 44 anodes. Cooled anodes are lifted from the bosh tanks by a 15-ton overhead crane.

Because of the smooth operation of the casting wheel, rolled edges are seldom formed and little trimming is required. Anodes are carefully inspected and loaded on railroad cars with vertical-lift storage battery trucks. The concrete floor adjacent to the casting wheel, armored with cast iron grids cast into the concrete, affords ample floor space for inspection and loading and an adjoining large concrete platform is available for anode storage when copper shipments are interrupted.

Copper pouring spoons are relined after each pour with a sand-cement mixture and pouring lips are renewed. The newly lined spoon is cured several days under a gas flame and is warmed up to operating temperature before being put into service. Anode molds, weighing about 5000 lb, are cast on the wheel as required, usually before the start of a regular pour. The average life of a mold is about 450 tons of anodes. During the copper pour, molds

Fig. 12—The rotating anode furnace, located in and adjacent to the converter aisle, has separate openings for poling and release of combustion gas. Blowing in this furnace is limited to cleaning up the charge and skimming off some slag before poling, as all sulphur is eliminated in the oxidizing furnace.

are sprayed while hot with a silica wash to prevent anodes from sticking to the molds.

The operation of the anode plant has been satisfactory in all respects. Repairs to refining and casting equipment have been light and production of high quality anodes has been consistent. Rejection of imperfect anodes has been negligible.

Waste Heat Boilers

Combustion gases from the reverberatory furnace pass through two waste heat boilers, the inlets to which are provided with water-cooled cut off dampers, making it possible to isolate completely either boiler for inspection or repairs. The boilers are not baffled and operate with a draft loss of 0.10 in. of water from inlet to outlet. Design pressure of the boilers is 950 psig, with superheater outlet conditions at 800 psig and 750°F.

Water walls in the furnace section have a heating area of 3730 sq ft per boiler and the boiler section 11,200 sq ft, making a total of 14,930 sq ft of heating area. Normal evaporation is 50,000 lb of water per hr per boiler, with a heat recovery representing 53.0 pct of total fuel used in the reverberatory furnace. Boiler feed water temperature is maintained at 325°F and enters the boiler at 1000 psig.

Fig. 13—Copper is cast at a rate of about 40 tons per hr into 700 lb anodes on this 22 mold anode casting wheel. Anode molds are cast on the wheel as required, and have a life of about 450 tons of anodes.

Water wall and slag screen tubes are cleaned with 24 soot blowers, while superheater elements and boiler tubes are equipped with 9 soot blowers in each boiler. Soot blowers are operated automatically from the boiler control panel, using superheated steam at 500 psig. Little hand lancing of boilers is required. Dust trapped in boilers is collected in gated hoppers and is dropped to the ground below where it is moistened with water and loaded into dump trucks. Reclaimed dust is mixed with converter flux in the crushing plant receiving bin and is resmelted in converters.

Flue System, Cottrell and Stack

Converter and reverberatory gases are discharged into separate steel balloon flues, 11½ ft in diameter. The two flues enter a common junction box at the Cottrell inlet, where a baffle system mixes the gases before entering the precipitation chamber. Heavy dust that settles to the bottom of the flues is removed by drag chains, reverberatory dust being discharged to the Cottrell blow tank system, while the converter dust is collected in a hopper from which it is removed by dump truck and returned to the converter aisle for resmelting. Stack and Cottrell temperatures have not as yet indicated the necessity for insulating either of the balloon flues.

Cottrell precipitation consists of six units of pipe treaters, each unit containing 120 12-in. vertical pipes 16 ft long. All units are parallel and down draft. The discharge electrode is a small chain suspended in the center of the 12-in. pipe. All units are hand rapped. Exit gases pass upward around the pipes and then laterally to and through the outlet flue into the chimney. A bypass flue, closed by a jug damper, may be used to pass gases directly into the treater outlet flue uptake, if necessary. Treater walls are acid-proof brick laid with acid-proof mortar.

Power to the treaters is furnished by two mechanical disk rectifiers, each of which is coupled to a 25-kva motor generator set, driven by a 40-hp motor. A third rectifier unit is available as a spare. An exciter furnishes the field for the generator. Two of the four leads from rectifier stationary shoes are connected to terminals of high voltage transformers which have taps ranging from 50,000 to 100,000 v. Normally the 62,500-v tap is used.

Converter gases entering the Cottrell treater vary over a fairly wide range, because of intermittent operation, having an average of 475°F. Reverberatory gas temperature is fairly uniform at about 495°F. Temperature of Cottrell outlet gas averages 430°F. Under present operating conditions, the volume of gas treated is approximately 340,000 cu ft per min, somewhat higher than the normal capacity of the precipitator. However treater efficiency is satisfactory, stack testing showing consistently a loss of less than ¼ of 1 pct of total plant copper input.

Cottrell dust is collected in hoppers, one under each treater unit. The dust is periodically dropped into McLeod blow tanks located under the hoppers and is pneumatically transported from one tank to another in series until it reaches the sixth tank. From the last tank in the series the dust is transported with high pressure air several hundred feet to a cyclone collector, which is equipped with wool filter bags, and is stored in a small bin. Once each shift the dust is withdrawn from the bin, moistened with spray water, put through a horizontal pug mill and delivered to the conveyor belt carrying concentrate into the smelter. Average dust recovery is about 6 tons per day.

The chimney is of tapered reinforced concrete construction, lined with acid-resisting brick laid in acid-proof mortar, and has 2 in. of fiber glass insulation between the concrete and the brick lining. The stack is 360 ft high, 24 ft ID at the bottom and 15 ft at the top. It is protected by lightning rods with copper cables to ground. A testing station is located 127 ft from the ground. At 425°F stack inlet temperature and 60°F outside temperature, total stack draft is 1.70 in. of water. Draft drop through the Cottrell plant is 1.10 in., and the remainder is divided between reverberatory and converter operation by automatically regulating the butterfly damper in the converter balloon flue.

Smelter Organization and Maintenance

Smelter operation is under the control of the general smelter foreman. The reverberatory, converter, and anode departments each have a general foreman, with shift foremen on each of the operating shifts. The crushing plant, mason crew, and Cottrell plant each have a day shift foreman. Testing work is carried on by the smelter engineer.

The reverberatory furnace floor is flushed with water each shift. Grated drainage openings connect with a launder system which discharges all floor cleanings into a concrete sump. A motor-driven pump, actuated by a float switch, delivers the accumulated washings to a concentrate storage tank from whence it is pumped periodically to the mill filter building and joined with current concentrates for return to the smelter. The concrete anode operating and trimming floor, the copper loading dock, and the area behind converters is swept daily with a power sweeper. The area under converters and the converter aisle is cleaned daily with a small bulldozer.

A small repair crew is maintained to take care of running repairs and minor alterations. Major repairs and alterations are handled by the general plant shops which also take care of mine and mill heavy maintenance work.

Summary

After more than two years of entirely successful operation, performance of the Ajo smelter, both from a metallurgical and an economical standpoint, clearly demonstrates that the original objectives have been satisfactorily achieved. Day to day smelting of concentrator output has resulted in a straight flow of copper-bearing material from the mine to finished anodes. Attainment of a relatively high smelting rate through the single reverberatory furnace and a high rate of copper production per man-shift has resulted in an overall cost of producing anodes from concentrates that is favorably comparable with costs achieved in the Corporation's multifurnace copper smelters.

Acknowledgments

The author of the general plan of the Ajo smelter was Charles R. Kuzell, General Manager of Phelps Dodge Corp., who also was responsible for the introduction of numerous innovations in smelting practice and design of smelter equipment. The development of these ideas was carried out by the Western Engineering Dept., under the direction of H. V. Kruse, Chief Mechanical Engineer. Structural design, and the design or selection and arrangement of electrical and auxiliary mechanical equipment and the construction program was under the direction of Wilbur Jurden, Consulting Engineer, New York. Mr. Jurden was represented in the field by Stewart Carpenter, Construction Engineer.

Effect of Dissolved Sulphur on the Surface Tension Of Liquid Copper

by C. F. Baes, Jr. and H. H. Kellogg

The effect of dissolved sulphur on the surface tension of liquid copper has been measured by a sessile-drop method at 1120°C. Sulphur is highly "surface active" in liquid copper; the surface tension lowering is about 650 dynes per cm for a sulphur content of 0.6 pct. The degree of adsorption of sulphur on the liquid copper surface has been calculated, and various models of the surface layer have been tested against the results.

THE science and technology of surface chemistry and physics at room temperature are relatively advanced, and the engineer possesses a background of information that allows him to predict and control many phenomena—such as frothing, emulsification, wetting of solids by liquids, flow through capillaries, adsorption, mineral flotation, penetration of porous bodies by liquids—which are related to the behavior at interfaces. Surface phenomena in high temperature systems are probably of equal importance to the metallurgist and ceramist, but at present are incompletely understood. Frothing of liquid slags, penetration of refractories by liquid metals and slags, infiltration of powder metallurgy "skeletons" by liquid metals, bonding of metals to ceramic oxides in the manufacture of "cermets," wetting of one metal by another for purposes of soldering and welding, are but a few of the many phenomena of metallurgy that are controlled by surface behavior.

Concerning the most elementary of surface properties—the gas-liquid surface tension—the existing data on liquid metals are inadequate. For the surface tension of "pure" metals the results of different investigators differ by 10 or 20 pct. The role of surface-active agents in liquid metals is relatively unknown, and it is not unlikely that the discrepancy in the values for the surface tension of pure metals is due to the presence of traces of surface-tension-lowering impurities in the samples. Based on analogy to room-temperature systems, the highly surface-active impurities in liquid metals should be

elements or compounds of limited solubility in the liquid metal and possessing considerably weaker intermolecular bonding forces than the metal itself. The nonmetals of the V, VI, and VII groups of the periodic table might be expected to act in this way.

The experimental work in this paper represents a study of the surface tension of pure liquid copper in hydrogen at 1120°C, and the effect of dissolved sulphur (which is a strongly surface-active agent in liquid copper) on the surface tension of copper. The Gibbs equation has been applied to the results and an attempt made to correlate the surface tension behavior with two models of the interfacial layer.

The sessile-drop method for surface-tension measurement at high temperatures which was used in this investigation has been described by several investigators.^{1,2} It involves the measurements of the dimensions of a stationary liquid drop on a horizontal surface. From these dimensions and the liquid density, the surface tension of the liquid may be calculated either by means of various approximate formulas, or more accurately by means of the Bashforth and Adams tables.³ For liquid drops which exhibit a contact angle greater than 90°, by far the simplest dimensions to measure are those indicated in Fig. 1, i.e., the diameter of the maximum horizontal cross section ($2X$) and the maximum height (Z) above this plane. In order to calculate the contact angle and the volume of the drop, the diameter at the base of the drop ($2a$) and the total height (h) also must be measured.

Upon investigation of the literature, the authors failed to discover a concise statement of the accuracy of the method when used in conjunction with the Bashforth and Adams tables, hence a careful examination of the tables was made and the curve shown in Fig. 2 was constructed. The "error factor," plotted as the ordinate, is the factor by which the

Discussion on this paper, TP 3497DE, may be sent, 2 copies, to AIME by July 1, 1953. Manuscript, Oct. 10, 1952. New York Meeting, February 1952.

Fig. 1—Diagrammatic representation of a sessile drop of liquid copper on a solid surface.

uncertainty in the experimental measurement X/Z (Fig. 1) is multiplied to obtain the uncertainty in the calculated surface-tension value (assuming no error in the liquid density). The curve clearly indicates the desirability of using drops of the maximum convenient size (thus of the maximum X/Z value).

Experimental

The experimental method involved the following steps: 1—the formation of a sessile drop (of approximately known sulphur content), at 1120°C under hydrogen, in a vacuum-tight furnace tube; 2—photographing the incandescent sessile-drop by means of a fixed-focus camera; 3—measurement of the resulting plates by means of a microcomparator; 4—microanalysis of the solidified drop for sulphur.

Apparatus: The furnace-tube assembly (Fig. 3) consisted of a fused-silica tube ($1\frac{3}{8}$ in. ID, $1\frac{3}{4}$ in. OD x 30 in.) with standard taper, 45/50 male joints ground at each end, which provided a vacuum-tight seal when assembled with the water-cooled female joints. The lubricant used in these joints (Apiezon "N" grade stopcock grease) retained its consistency when the furnace was in operation, provided cooling water was passed through the water jackets continuously. The temperature of the central portion of the furnace tube was controlled to $\pm 3^{\circ}\text{C}$ by means of a Brown temperature-controller activated by a chromel-alumel thermocouple inserted in a silica thermocouple tube. The thermocouple tube

Fig. 2—Error factor as a function of the drop dimensions, X/Z .

contained a silica-pyrex graded seal near the ground joint. The thermocouple was repeatedly checked by noting the temperature reading at which the copper sample began to melt (melting point, 1083°C). The resistance furnace was constructed of a nichrome-wound alumina core packed in insulating brick. The pumping system consisted of a fore pump and a three-stage oil diffusion pump. The all-glass vacuum system, used in conjunction with the vacuum furnace, contained a CaSO_4 and a P_2O_5 drying column through which H_2 was introduced, a Töpler pump for regulating gas pressures, and a McCleod gage. The entire system could be easily pumped down to a "stick" vacuum when the furnace tube was at room temperature; however, when the furnace tube was at 1120°C , the ultimate vacuum obtainable, as indicated by the McCleod gage, was of the order of 10^{-5} mm of Hg.

The Optical System: The incandescent sessile drop was viewed through an optically flat window (surfaces parallel to 30 sec of arc) cemented at the end of the furnace-tube assembly with "Glyptal" cement. For the production of a well-corrected image, it is essential that such a window have optically flat surfaces of good parallelism. The camera, which was mounted directly behind the furnace-tube assembly, consisted of an F:9 "Artar" apochromatic photoengraving lens of focal length 14 in., and a plate holder mounted at opposite ends of a brass tube. Focusing was accomplished by means of a screw-thread adjustment which permitted the entire camera assembly to be moved parallel to the optical axis. The plate distance was fixed at about 42 in., giving an object distance of approximately 21 in., and a magnification of about 2.

Due to the sensitivity of the highly fluid molten drops to vibration, it was found necessary to place the bench, on which the apparatus was mounted, upon sponge-rubber mats.

Preparation and Purification of Materials: All of the copper samples used in these measurements were cut from a single piece of highly purified electrolytic copper, supplied by the Research Dept. of Phelps Dodge Corp. The reported analysis indicated that all impurities other than oxygen totaled 0.0053 pct. Each sample was first cleaned in 1:1 HNO_3 , then in 1:1 HCl , and finally rinsed in distilled water. Copper-plated tools were used in all subsequent handling of the sample. The Cu_2S was prepared by first precipitating CuS from dilute sulphuric acid solution of reagent grade $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$ with H_2S . The filtered and washed precipitate was then mixed with sulphur and ignited in an alumina crucible at 1200°C for 30 min. Analysis of the resulting matte indicated 21.7 pct S.

Experimental Procedure: The weighed sample strip (1 to 3 g) was wound into a tight spiral and placed on the plaque, a 1x1 in. clear-silica plate polished to a mirror finish. A weighed amount of Cu_2S was deposited within the center of the spiral, the plaque and sample were placed on the silica plaque support and moved to the center of the furnace tube. The apparatus was assembled, opened to the vacuum pumps, and the heating current was turned on. During the heating period, the plaque surface was carefully leveled by rotating the furnace tube about its axis until tests of the image on the ground glass, using a small level, indicated the surface of the plaque to be horizontal in the direction at right angles to the optical axis. Leveling of the plaque along the optical axis could be accomplished by

slightly raising or lowering the free end of the furnace-tube assembly, and then focusing on the ground glass the front and back edges of the plaque to check their relative heights. The system was pumped out continuously until the temperature reached 700° to 800°C and then was flushed with several batches of dry hydrogen. The hydrogen pressure was finally adjusted to 50 mm Hg. The heating rate was decreased when the melting point was reached since it was found that movement of the sample, caused by rapid and uneven melting, often resulted in the sample falling off the plaque. The drop was maintained at 1120°C for 15 min before the first photograph was taken. The image of the drop was very carefully focused on the ground glass with the aid of a 15-X microscope eyepiece placed on the clear central portion of the glass. Focusing at full aperture could be done with an accuracy of at least $\pm \frac{3}{4}$ turn of the focusing screw (± 0.64 mm) which permits a reproducible magnification to within ± 1.2 parts per thousand. Usually two photographs were taken at a 15-min interval. Immediately after the last exposure, the heating current was turned off and the system cooled to room temperature. Kodak "M" plates ($3\frac{1}{4} \times 4\frac{1}{4}$ in.) were used with an exposure of $\frac{1}{2}$ sec at f:16, and were developed in Kodak "Microdol."

Measurements and Calculations: The microcomparator (a "Toolmaker's Microscope," manufactured by Bausch and Lomb) used in this work was provided with micrometer screw adjustments for measuring both horizontal and vertical distances on the plates. The plate to be measured was mounted on the instrument with the base of the drop-image parallel to the horizontal axis of the stage. The only measurement which presented any difficulty was that of Z (Fig. 1). Because of the uncertainty in locating the vertical coordinate of the tangent point, it is by far the less accurate of the two measurements required for the surface tension calculation. The procedure which was used to locate the point b is as follows (cf. Fig. 4): The horizontal micrometer screw was adjusted until the vertical cross hair was coincident with the edge of the drop in the region of the tangent point. The plate was then moved horizontally a distance c (e.g., 0.005 in.), such that the vertical cross hair intersected the drop surface above and below the tangent point. The vertical coordinates (d and e) of these intercepts were measured; then the stage was again moved horizontally the fixed distance c in the same direc-

tion and the new intercepts read. The process was repeated until five sets of coordinates were obtained for each side of the drop. The coordinate f in Fig. 4 is the mean value of the coordinates d and e . Corresponding f values for each edge of the drop were averaged and plotted against the distance the vertical cross hair had been displaced from the edge of the drop. The resulting nearly straight line was extrapolated to zero to obtain b . The reproducibility of the Z values obtained in this way was about 4 to 6 ppt (parts per thousand), while the X values could be measured to at least 1 ppt. The accuracy of the $2a$ and h values (Fig. 1) was limited to approximately 5 ppt by the relatively poor definition of the image in the region of the base of the drop. The calculation of the data, while straightforward, is too lengthy to be presented here. The method is described by Ellefson and Taylor.¹ A liquid-density value of 7.90 g per cu cm was used in all the calculations.⁴ While the presence of 0 to 0.8 pct S in liquid copper will quite probably change the density, it is believed that this effect will be quite small. Attempts were made to determine the density of the individual liquid drops by calculation of the volume and measurement of the weight of the solidified drops, but the results were scattered and generally low. The lack of precision, while caused in part by the poor accuracy of the a and h values, resulted mainly from gas bubbles trapped within the drop at the liquid-solid interface (*vide infra*).

Experimental Results: Surface tension measurements of liquid copper drops containing 0.0055 to 0.83 pct S, as well as measurements on pure copper drops, are presented in Table I. The surface tension lowering, F , is plotted as a function of final sulphur concentration in Fig. 5.

Preliminary sessile-drop measurements, made by means of a less refined apparatus, served to show that the surface tension of copper in vacuo is not

Fig. 4—Sketch showing method of locating the vertical coordinate of the tangent point on a liquid drop.

Fig. 5—Surface-tension lowering, F , of liquid copper as a function of the sulphur content. Circles are experimental points; the solid line is calculated from the relation: $\log C_s = 3.9 \log F - 11.27$.

greatly different from the values shown in the table for the sulphur-free samples. Measurements in the presence of nitrogen and argon were inconclusive because of traces of oxygen in the system, partly as impurities in the gases and partly from the permeability of the silica tube to air at the operating temperature. The presence of a trace of oxygen in the system led to irreversible slagging at the copper-silica interface and a dull appearance of the cooled drop. This slagging was a remarkable effect in that the cooled drop adhered to the plaque so strongly that when it was pried loose a quantity of silica adhered to the base of the drop. On the basis of the less accurate measurements, it appears that in cases of appreciable slagging, the surface tension of copper is lowered about 100 to 300 dynes per cm. Only when the sample was melted in hydrogen was slag formation eliminated. While the cooled drop often adhered to the plaque, it usually could be removed easily, leaving the silica surface unaffected, and the copper surface smooth and shiny. The variability of the contact angles listed in the table may be caused in part by traces of slag formation, but the agreement among the three runs on pure copper indicates the surface tension effect to be small.

With one exception, chemical analyses* of the

* These microanalyses were performed by Dr. C. Tiedcke, Teaneck, N. J. An accuracy of ± 2 pct of the absolute value is claimed.

cooled drops indicate that an appreciable loss of sulphur occurred during the course of each run. Rough calculations, based on the Cu_2S volatility data of Hsiao and Schlechten,⁶ indicate that losses due to volatilization and decomposition of Cu_2S during the heating period, prior to the introduction of hydrogen were not appreciable.

While considerable losses of sulphur to the gas phase may be expected as a result of the reaction

calculations based on the data of Sudo⁶ and Rosenqvist⁷ for the equilibrium of the reaction

indicate that after the sample has melted the total amount of H_2S in the gas phase would, in general, decrease to less than 2 pct of the sulphur content of the drop. However, inspection of the furnace tube after each run revealed small deposits of copper and copper sulphide which had condensed on the cooler

portions of the inner wall. In addition, appreciable amounts of material were thrown off from the sample during the melting process, even when the heating rate was reduced to a practical minimum. It is probably this effect, along with transfer of sulphur to the cooler portions of the furnace tube, which is primarily responsible for the generally lower final sulphur contents, especially since the undissolved Cu_2S in a partially melted sample floats on the molten surface as small crystals which are easily thrown off by surface eruptions. To decrease transfer of sulphur to and from the walls, the tube was frequently cleaned (with only partial success) and generally the runs were made in order of increasing sulphur content. An exception to this procedure was run No. 4. While this run was preceded by careful cleaning of the tube, it is apparent that sulphur was transferred to the drop during the run. The final sulphur content of the samples has in every case been taken as that corresponding to the measured surface tension values, since the good agreement between the duplicate surface tension measurements for each run indicates that no appreciable change in sulphur content occurred after the sample had melted, and since little change in composition could occur after the cooling drop had solidified.

The dimensions of a given drop often changed considerably between successive photographs in such a way as to suggest that a gas bubble was trapped in the drop. Indeed upon examination of the solidified drop, large cavities were often found at the metal-silica interface. In view of the large contact angles found for these drops, it is not surprising that such gas bubbles are stable. However, their presence would not be expected to affect the measured surface tension of these drops and, indeed, this is borne out by the general agreement between the values found for a given sample at successive time intervals.

It is clear from Fig. 5 that the presence of sulphur as an impurity in the pure copper samples would affect the surface tension values, and make necessary an additive correction to all of the F values. However, such a correction would not affect the

quantity dF/dc , which appears in the Gibbs equation. Impurities other than sulphur in the pure copper sample, will likewise have a negligible effect on dF/dc , since they are present in virtually the same concentration in all of the samples.

The uncertainties indicated in the table for the surface tension values have been obtained by use of the curve in Fig. 2. The corresponding uncertainties in the surface tension lowering, (F), are represented approximately by the size of the circles in Figs. 5 and 6.

Discussion of Results

The value listed in Table I for the surface tension of pure copper in hydrogen at 1120°C (1269 dynes per cm) is considerably higher than previously reported values. Thus, Sauerwald, et al.⁸ report 1150 dynes per cm at 1115°C; Becker, Harder and Kornfeld,² who used the sessile-drop method with the sample in argon, find 1038 dynes per cm at 1150°C. Since the effects of various gases such as nitrogen, hydrogen, and argon on liquid-metal surface tensions are by no means well known, it is not possible at this time to compare critically these different values for copper. However, when conflicting values of surface tension of a pure liquid are encountered, the highest value should be preferred, since traces of impurities may well lower the surface tension appreciably, but can have only a negligible effect toward raising it.

Application of the Gibbs equation to the system Cu-S-H at constant temperature leads to the result

$$-d\gamma = dF = \Gamma_1 d\mu_1 + \Gamma_2 d\mu_2 + \Gamma_3 d\mu_3 \quad [3]$$

wherein Γ_1 , Γ_2 , and Γ_3 denote the excess surface concentrations of copper, sulphur, and hydrogen, and μ_1 , μ_2 , and μ_3 denote the partial molal free energies of the three components. For the dilute solutions of sulphur used in the present experiments it may be assumed that the activity of copper is constant. The results of Schuhmann and Moles⁹ establish that even in a saturated solution of sulphur in liquid copper at these temperatures, the H_2S/H_2 ratio in equilibrium with the solution is approximately 4×10^{-3} . Since the present experiments were conducted at a constant H_2 pressure (50 mm Hg), the hydrogen activity in the system may reasonably be assumed constant. Thus, Eq. 3 reduces to

$$dF = \Gamma_2 d\mu_2 \quad [4]$$

By incorporating the approximate proportionality of the sulphur activity to the sulphur concentration, reported by Rosenqvist⁷ and Sudo,⁶ Eq. 4 becomes

$$dF = \Gamma_2 RT d \ln C_2 \quad [5]$$

where C_2 denotes the pct S in the liquid copper. This is the so-called approximate form of the Gibbs equation. Two rearrangements of Eq. 5 will aid in the correlation of the data:

$$\frac{dF}{dC_2} = \frac{\Gamma_2 RT}{C_2} \quad [6]$$

$$\frac{d \ln C_2}{d \ln F} = \frac{F}{\Gamma_2 RT} \quad [7]$$

In low temperature systems it is often the case that F is proportional to C_2 at low concentrations. Thus in Eq. 6 dF/dC_2 may be replaced by F/C_2 and the following relation is obtained:

$$\frac{F}{\Gamma_2} = RT, \text{ or } FA_2 = RT \quad [8]$$

where A_2 is the reciprocal of Γ_2 , or the area per mol of adsorbed material. Systems which behave according to Eq. 8 have been interpreted on the basis of a surface film of the order of one molecular diameter in thickness in which the adsorbed substance behaves as an ideal two-dimensional gas.

It is evident from Fig. 5, where F is plotted as a function of C_2 , that even in the very low concentration region, the relation of F to C_2 is far from linear. The ideal two-dimensional gas model, represented by Eq. 8, is, therefore, not applicable to these data.

In Fig. 6, the data are plotted as $\log C_2$ vs $\log F$. Within the uncertainty of the data, the relation is

Fig. 6—Log F vs $\log C_2$. Circles are experimental points. The straight line is expressed by: $\log C_2 = 3.9 \log F - 11.27$.

linear with a slope of 3.9. The deviation shown by the lowest point is not serious in view of its uncertainty. The deviation of the point at 0.12 pct S might well be disregarded on the grounds that the sulphur analysis for this sample is anomalous; thus, it is much lower relative to the starting composition for this run than are any of the other analyses. The curves in Fig. 5 have been constructed from the straight-line plot in Fig. 6 ($\log C_2 = 3.9 \log F - 11.27$) and the fit is quite satisfactory except for the two points already mentioned.

If the experimentally found value of $d \ln C_2 / d \ln F$ is now incorporated in Eq. 7, the following relation is obtained:

$$3.9RT = \frac{F}{\Gamma_2}$$

or

$$3.9RT = FA_2 \quad [9]$$

Eq. 9, which correlates the present data, bears a formal relationship to the Schofield and Rideal equation¹⁰

$$F(A_2 - B) = iRT \quad [10]$$

which purports to describe the behavior of a non-ideal gaseous adsorbed-film on a liquid surface. In Eq. 10 B is a constant which represents the limiting area of the surface-active material, and $1/i$ is a measure of the lateral molecular-cohesion. Eq. 9 reduces to Eq. 10 if B is zero and i is 3.9. A value of i greater than unity is meaningless, however, since it would indicate a molecular repulsion rather than a cohesion, hence the Schofield-Rideal equation does not aid in the interpretation of the present results.

Fig. 7—The surface-excess concentration of sulphur, Γ_2 , as a function of the bulk concentration of sulphur, C_2 . Calculated from the relation: $\Gamma_2 = KC_2^{1/3.9}$. The horizontal dashed line represents the surface-excess concentration of sulphur which would result from a close-packed monolayer of sulphur atoms.

The relation between the bulk concentration, C_2 , and the surface excess-concentration, Γ_2 , which applies to the present data may be derived as follows:

From Eq. 9

$$\log \Gamma_2 + \log 3.9RT = \log F \quad [11]$$

If Eq. 11 is combined with the experimental relation

$$\log C_2 = 3.9 \log F - 11.27$$

the result is

$$\log \Gamma_2 = \frac{1}{3.9} \log C_2 - \log 3.9RT + \frac{11.27}{3.9}$$

or

$$\Gamma_2 = KC_2^{1/3.9} \quad [12]$$

where $K = \frac{782}{3.9RT}$ and has the value 1.74×10^{-9}

when R is expressed in ergs per mol per °K. Fig. 7, which shows graphically the relation between C_2 and Γ_2 , was calculated from Eq. 12.

Based on the recent measurements of Rosenqvist⁷ and Schuhmann and Moles⁸ the solubility of sulphur in liquid copper is probably about 1 pct at 1200°C. If this value is used without correction for the present work at 1120°C, then Fig. 7 indicates the maximum surface excess of sulphur to be 1.74×10^{-9} moles per sq cm. This compares favorably with the value expected for a hexagonal close-packed monolayer of sulphur atoms — 1.4×10^{-9} moles per sq cm (calculated with a van der Waals radius of 1.85Å), represented by the horizontal dashed line in Fig. 7. In all probability the surface excess of sulphur is not confined to a monolayer, hence the fact that the calculated surface excess exceeds the amount that can be held in a close-packed monolayer does not invalidate the results.

The adsorption equation (Eq. 12) found to apply to the present data is identical to the Freundlich adsorption isotherm, and is similar in form to the equation which represents the distribution equilibrium of a solute between two phases when the solute is associated in one phase into groups of n atoms (n is 3.9 in Eq. 12). This suggests one possible model which would correlate the results in the Cu-S adsorption system. If the sulphur in the bulk solution is associated into groups containing four atoms of sulphur, while the sulphur in the surface film is un-

associated, then the distribution between the bulk and the surface would take the form

$$k = \frac{\text{activity of sulphur in bulk}}{(\text{activity of sulphur in surface})^4}$$

Assuming a Henry law relationship to apply,

$$k' = \frac{C_2}{\Gamma_2^4}, \text{ or } \Gamma_2 = k'' C_2^{1/4} \quad [13]$$

Association of sulphur into groups of four atoms is unlikely, however, in view of the results of Sudo⁶ and Rosenqvist⁷ on sulphur activity.

A further correlation that may be significant is the near equality of the free-surface energy of ad-

sorption per atom of sulphur, $\frac{3.9RT}{N_{\text{avg}}}$, which is

7.5×10^{-13} ergs, and the free surface energy of pure liquid copper per atom of copper, which is 7.8×10^{-13} ergs.[†] The agreement between these values suggests

[†] The number of copper atoms per sq cm of surface = $0.918 \left[\frac{N_{\text{avg}} \cdot d}{M} \right]^{2/3} = 1.63 \times 10^{15}$, where d is the liquid density and M the atomic weight of copper. The factor 0.918 is a packing factor for hexagonal closest packing.

$$\frac{\text{Surface tension of pure copper}}{\text{No. of copper atoms per sq cm}} = \frac{1269}{1.63 \times 10^{15}} = 7.8 \times 10^{-13} \text{ ergs.}$$

that, atom for atom, the adsorbed sulphur dissipates nearly all of the free electrovalent forces of copper which give rise to the surface tension.

More experimental data on this and similar systems are needed in order to establish a consistent model for the surface-active behavior of the group VI elements in liquid copper. Preliminary experiments with selenium as an impurity¹¹ have shown this element to behave in a manner almost identical to sulphur. Experiments with oxygen as the impurity have failed due to inability to find a solid surface which is inert towards liquid copper containing dissolved oxygen.

Metallic Oxidation in Chromium Steel Melting

by D. C. Hilty, G. W. Healy, and Walter Crafts

By means of a theoretical extension of the Cr-C temperature relation in molten chromium steels to low chromium contents and by a correlation of the ratios of chromium to iron in the slag and metal, a method has been developed for estimating the amount of metallic oxidation during the oxidizing period of a chromium steel heat. Application of this method has indicated that due to temperature limitations metallic oxidation may be excessive for very low carbon steels charged with more than a small amount of chromium.

IN the melting and refining of chromium steels the oxidation of carbon to a low level is accompanied by the oxidation of chromium and iron in considerable amounts. For the subsequent recovery of chromium and associated iron from the slag, the amounts of metal oxidized must be known for efficient reduction and control of composition. Further, in order to arrive at an accurate understanding of the process, so that chromium-bearing scrap can be used effectively, information is required on the relation between composition of the charge and weight of metal oxidized to reach the desired carbon content.

Crafts and Rassbach¹ recently developed an empirical relation between chromium, iron, and manganese oxidized per ton of steel charged, and final carbon content and temperature. This relation did not show any dependence on amount of chromium charged. However, it was felt that such a dependence might be present, so a further analysis of the data was undertaken.

Cr-C Relation at Low Chromium Levels

Crafts and Rassbach's results were based on temperatures estimated from the Cr-C relation previously established experimentally by Hilty,² and on a single temperature observation (immersion thermocouple) on a heat made at low temperature from a charge of carbon steel scrap containing only a small amount of residual chromium. The temperatures estimated from the Cr-C relation were for heats charged with chromium-bearing scrap and which contained substantial amounts of chromium (2 to 10 pct) at the end of the oxidizing period. No

data, other than that from the low temperature heat just mentioned, were available for the low and intermediate chromium ranges.

In order to extend the range in which temperature may be estimated, the Cr-C relation requires further consideration. The Cr-C relation, expressed as

$$K = \frac{\% \text{ Cr}}{\% \text{ C}}; \log K = -\frac{15,200}{T} + 9.46 \quad [1]$$

suggests that carbon is zero at zero chromium in the bath. This is obviously absurd, because as chromium approaches zero the carbon content must approach the limit established by the Fe-C-O equilibrium. It is evident, therefore, that the Cr-C relation as defined by Eq. 1 is not valid below some minimum chromium content that may vary with temperature. On the other hand, it is probable that any such limiting chromium content is less than 4 pct at 3200°F, since the experimental data from which the Cr-C relation was derived included several observations at that level with no deviation. In any event, it is apparent that further evaluation of the results presented by Crafts and Rassbach is dependent upon a means for estimating the Cr-C temperature relation in the low chromium region.

From the observations of Chen and Chipman³ and thermodynamic data given in *Basic Open Hearth Steelmaking*,⁴ the following relation can be calculated for melts containing small amounts of chromium and carbon assuming a carbon monoxide pressure of 1 atm:

$$K^1 = \frac{\% \text{ Cr}}{(\% \text{ C})^2}; \log K^1 = \frac{-21,250}{T} + 13.88 \quad [2]$$

Moreover, by plotting Eq. 2 for any given temperature on cartesian coordinates, it can be extrapolated graphically to the limiting carbon content at zero chromium for the specified temperature without serious complications.

By means of Eq. 2 and its extrapolation, the Cr-C temperature relations originally established experi-

Fig. 1—Approximate Cr-C-temperature relations for all chromium contents of interest in the melting of chromium steels.

mentally at moderate to high chromium levels can be extended through the range of low chromium concentration as shown in Fig. 1. It is emphasized that the dashed curves of Fig. 1 are only approximations of the true Cr-C relations at low chromium contents. Nevertheless, they appear to be of a rea-

Table I. Analytical Results on Samples

sonable order and are considered quite useful for practical purposes.

Effect of Manganese

The similarity in the relative deoxidizing powers of manganese and chromium in liquid iron is demonstrated by the work of Hilty and Crafts⁵ on manganese and that of Chen and Chipman on chromium. Moreover, Hilty pointed out the resemblance between the heat of formation calculated for the chromous oxide assumed in order to explain his experimental results and that of manganous oxide. In

addition, arc-furnace heats made by oxygen-blowing practice from charges containing several percentages of manganese as well as chromium-bearing scrap have contained total chromium plus manganese contents at the end of the oxidizing period equal to the chromium contents alone in similar heats made in the same furnace from low manganese charges oxidized to the same carbon levels with the same rate of oxygen input. Consequently, it is considered that the moderate concentrations of manganese usually found in chromium-steel heats are substantially equivalent to similar quantities of chromium and should be added to the chromium for practical applications of Fig. 1. They have been so considered in the arc-furnace data described below.

In this regard it is notable that the four data points spotted in at the very low chromium level in Fig. 1 refer to a laboratory heat that contained a small, but presumably effective, amount of manganese. These data were obtained from a 100-lb induction furnace heat charged with Armco iron and a small amount of high carbon ferrochromium. The heat was held at relatively constant temperature in the open. Samples were taken by the Taylor sampling technique and temperatures were measured by means of Pt-Pt-10 pct Rh thermocouples. Analytical results on the samples are given in Table I. These results agree fairly well with the curves in Fig. 1. The agreement, however, may be fortuitous because of analytical uncertainty and limited understanding of the controlling reactions.

Effect of Metal Composition on Ratio of Cr + Mn to Fe in Slag

Fairly complete data for 27 arc-furnace heats described by Crafts and Rassbach were available. These heats were made in a 2000-lb capacity, magnesite-lined, arc furnace from charges containing various amounts of chromium and nickel as shown in Table II. After meltdown, all heats were blown with oxygen in order to lower their carbon contents. Analytical results from slag and metal samples taken at the end of the oxidizing period are tabulated in Table II.

* Charge weight plus 9 lb average pickup from lining except Heat 27, obtained from material balance.

† Estimated 0.50 pct Mn in charge except Heat 27, obtained from material balance.

Ratios of the chromium plus manganese to iron contents of the slag were plotted as a function of those of the metal with the result illustrated by Fig. 2.

The data are adequately represented by the line of regression whose equation is

$$\log \frac{(\% \text{ Cr} + \% \text{ Mn})}{(\% \text{ Fe})} \text{ in slag} = 0.812 \log \frac{[\% \text{ Cr} + \% \text{ Mn}]}{[\% \text{ Fe}]} \text{ in metal} + 1.238 \quad [3]$$

Although it appears that the points might be fitted better by two intersecting lines, such a representation is not justified statistically.

The excellent correlation evident in Fig. 2 is rather surprising, especially since the heats covered rather broad ranges of both composition and, presumably, temperature. Apparently however, the relative proportions of chromium (plus manganese) and iron in the slag are controlled almost entirely by the amounts of chromium (plus manganese) and iron in the metal without regard to carbon content or apparent temperature.

Weight of Metal Oxidized

The relation shown in Fig. 2 considerably simplifies the task of calculating the weight of metallics oxidized during the oxidizing period of a chromium-steel heat. In order to perform such a calculation, it is necessary to know only the amounts of chromium and manganese in the charge in addition to the metal composition at the end of the oxidizing period according to the following formula, the derivation of which is shown in the Appendix:

Pounds (Cr+Mn+Fe) oxidized per ton of charge

$$= 2000 \frac{(\text{Cr}_1 + \text{Mn}_1) - (\text{Cr}_2 + \text{Mn}_2)}{\frac{100S}{1+S} - (\text{Cr}_2 + \text{Mn}_2)} \quad [4]$$

where Cr_1 is the percentage of chromium in the charge; Mn_1 , the percentage of manganese in the charge; Cr_2 , the percentage of chromium in the bath after oxidation; Mn_2 , the percentage of manganese

in the bath after oxidizing; and $S = \frac{(\% \text{ Cr} + \% \text{ Mn})}{(\% \text{ Fe})}$

in slag after oxidation which can be calculated from the bath composition by Eq. 3 or read from Fig. 2.

In Fig. 3 is shown the correlation of metallic oxidation of the heats in Table II calculated by Eq. 4 with the observations of Crafts and Rassbach. In general, the correlation is good. The deviations are easily explained by the rather arbitrary assumption of 0.50 pct Mn in the charge for most of the heats and by the lack of adequate tracers such as nickel to assist in calculating material balances for most of the low chromium, low nickel charge heats.

With the additional help of Fig. 1, for estimation of residual chromium after the oxygen blow, the amount of metallic oxidation can now be calculated for charges of varying chromium contents oxidized to specified carbon and temperature levels. The results of such calculations are shown in Figs. 4 and 5 for 0.015 and 0.05 pct C, respectively.

The substantial effect of charged chromium as well as the effects of the carbon content and temperature attained on the oxidation losses is apparent.

Fig. 2—Correlation of rates of chromium plus manganese to iron in slag and metal.

These illustrations strongly imply that avoidance of excessive oxidation loss in making very low carbon steel from a high-chromium charge may involve temperatures beyond the scope of usual steelmaking furnaces. Consequently, it would appear desirable to regulate the amount of chromium in a charge with due regard to the carbon content of the steel being made and the maximum safe operating temperature of the furnace.

In rationalizing the above results, it is presumed that the Cr-C temperature relation of Fig. 1 refers approximately to a state of equilibrium wherein the metal phase is saturated with an oxide of chromium as well as carbon monoxide. If, however, the chromium content of the bath after oxidation is less than that specified by the carbon content and temperature so that the metal is not saturated with a chromium oxide—as may well be the case in heats made at fairly high temperatures from low chromium charges—then Fig. 2 and Eq. 4 do not apply. Under such conditions, the chromium content of the bath may be controlled by other factors such as slag basicity, etc., in a manner analogous to the case of residual manganese in the open hearth. It would also appear that the relations shown in Figs. 1 and 2

Fig. 3—Correlation of estimated with actual metallics oxidized.

Fig. 4—Estimation of metal oxidized in blowing with oxygen to 0.015 pct C.

are of practical significance only when oxidation is carried out to such a degree that a significant proportion of the charged chromium is oxidized. For this reason the minimum amount of metal oxidized has been limited to 100 lb per ton in Figs. 4 and 5.

The temperature dependence of metallic oxidation indicated by Figs. 4 and 5 differs somewhat from the empirical relation reported by Crafts and Rassbach. Moreover, it is indicated to vary with the amount of chromium charged. A probable explanation of the differences is that among the heats used by Crafts and Rassbach to estimate the temperature coefficient most of the heats with higher chromium charges also reached higher temperatures at the end of the oxidizing period. Such a result would be expected for heats made under the same conditions with regard to oxygen input, etc., because of the relatively higher heat of oxidation of chromium. Thus, under practical operating conditions, the effect of increased chromium in the charge on metallic oxidation would be offset by the higher temperature attained during oxidation. The relation presented by Crafts and Rassbach is believed to illustrate the net result of regulating the amount of chromium in a charge with regard to the carbon content of the steel being made as suggested by Figs. 4 and 5 of this paper.

Fig. 5—Estimation of metal oxidized in blowing with oxygen to 0.05 pct C.

Summary

By means of published thermodynamic data an approximate Cr-C temperature relation for molten chromium steel under oxidizing conditions has been derived for the range of low chromium concentrations where the relation established experimentally at higher chromium levels is believed to be invalid.

The ratio of chromium (plus manganese) to iron in the slag of a chromium steel heat has been shown to depend almost entirely on the ratio of chromium (plus manganese) to iron in the metal. Through this relationship an expression for calculating the metallic oxidation during the oxidizing period of a heat has been derived.

It has been demonstrated that the amount of metallic oxidation is dependent upon the amount of chromium in the charge and the carbon content and temperature of the bath at the end of the oxidizing period. It is inferred that for steels oxidized to very low carbon contents from charges containing more than a small amount of chromium, metallic oxidation may be excessive because of maximum temperature limitations imposed by operating conditions.

Acknowledgments

The authors wish to express their appreciation for the valuable suggestions and criticism of John Chipman, Head, Dept. of Metallurgy, Massachusetts Institute of Technology, for the assistance received from H. J. O'Connor, Electro Metallurgical Co., in statistical studies, and particularly for the stimulating appraisal of the practical aspects of the problem by H. P. Rassbach, Electro Metallurgical Co.

Appendix

Derivation of Formula for Pounds of Metal Oxidized

Assume a charge weight of 2000 lb. Let the percentage of chromium plus the percentage of manganese in the charge be Cr_1 . Then the pounds of chromium plus manganese in the charge are

$$\text{Lb Cr + Mn charged} = 2000 \times \frac{Cr_1}{100} = 20 Cr_1 \quad [5]$$

Let X equal the pounds of chromium and manganese oxidized, and Y the pounds of iron oxidized. Then the weight of metal after oxidation will be

$$\text{Lb metal after oxidation} = 2000 - X - Y \quad [6]$$

It was shown that the ratio of chromium plus manganese to iron in the slag after oxidation can be estimated from the ratio of chromium plus manganese to iron in the metal (Fig. 2). Let S be the ratio of chromium plus manganese to iron in the slag. Then

$$\frac{\text{Lb Cr + Mn in slag}}{\text{Lb Fe in slag}} = \frac{X}{Y} = S \quad [7]$$

Eq. 6 can then be written in the form

Lb metal after oxidation =

$$2000 - X - \frac{X}{S} = 2000 - X \frac{1 + S}{S} \quad [8]$$

Let Cr_2 be the percentage of chromium plus manganese in the metal after oxidation. The weight can then be calculated from Eq. 8.

Lb Cr + Mn in metal after oxidation =

$$\left(2000 - X \frac{1 + S}{S} \right) \frac{Cr_2}{100} \quad [9]$$

But the amount of chromium plus manganese in the bath is also equal to the difference between the amount

originally charged (Eq. 5) and the amount oxidized designated by X .

$$\text{Lb Cr} + \text{Mn in metal after oxidation} = 20 \text{ Cr}_1 - X \quad [10]$$

Combining Eqs. 9 and 10, it is possible to solve for X

$$\begin{aligned} 20 \text{ Cr}_1 - X &= \left(2000 - X \frac{1+S}{S} \right) \frac{\text{Cr}_2}{100} \\ &= 20 \text{ Cr}_2 - X \frac{1+S}{S} \frac{\text{Cr}_2}{100} \end{aligned} \quad [11]$$

Hence

$$X \left(1 - \frac{1+S}{S} \frac{\text{Cr}_2}{100} \right) = 20 (\text{Cr}_1 - \text{Cr}_2)$$

$$\begin{aligned} \text{Lb Cr} + \text{Mn oxidized: } X &= \frac{(\text{Cr}_1 - \text{Cr}_2)}{1 - \frac{1+S}{S} \frac{\text{Cr}_2}{100}} \\ \text{or} \end{aligned}$$

$$X = 2000 \frac{\text{Cr}_1 - \text{Cr}_2}{100 - \frac{1+S}{S} \text{Cr}_2} \quad [12]$$

Since total weight oxidized is $X + Y$ and since $S = X/Y$, the total weight oxidized becomes

$$X \left(1 + \frac{1}{S} \right) = X \frac{1+S}{S} \quad [13]$$

Multiplying Eq. 12 by this factor $\frac{1+S}{S}$ then results in

$$\text{Lb metal oxidized} = 2000 \frac{\text{Cr}_1 - \text{Cr}_2}{\frac{100S}{1+S} - \text{Cr}_2} \quad [14]$$

In this equation Cr_1 is known from charge composition, Cr_2 from the analysis after oxidation, and S can be estimated from $[\% \text{ Cr} + \% \text{ Mn}]/[\% \text{ Fe}]$ in the metal after oxidation, using Fig. 2.

Example: A heat containing 11.5 pct Cr and 0.5 pct Mn in the charge is blown with oxygen to 0.05 pct C, reaching a temperature of 3200°F. From Fig. 1 $\text{Cr}_2 = 4.7$ pct is obtained. If there is no nickel in the heat,

$$\frac{\% \text{ Cr} + \% \text{ Mn}}{\% \text{ Fe}} = \frac{4.7}{100 - 4.7} = 0.049$$

Entering Fig. 2 at 0.049, S is estimated as 1.47. Then weight oxidized is

$$W = 2000 \frac{(11.5 + 0.5) - 4.7}{\frac{100 \times 1.47}{1 + 1.47} - 4.7} = 266 \text{ lb per ton charged.}$$

Technical Note

Note on Contamination of Silicon Ingots

by G. Sandoz and H. E. Stauss

THE purpose of this note is to draw attention to the possibility that a melt may be contaminated by a material not in direct contact with it by means of gaseous intermediate agents. In recent years silicon has assumed a position of importance because of its use in rectifiers and transistors and close attention has been required to control of both purification and contamination during all stages of preparation.¹ This note reports the observation that a graphite heater may have contaminated silicon ingots without direct physical contact through reactions that developed gaseous products.

Several ingots made with the equipment of Hino and Stauss,² using a graphite heater in a dried helium atmosphere, were found to have a small amount of a very hard substance on the free surface. X-ray analysis by F. W. von Batchelder showed the sub-

stance to be SiC. Similar contamination was not found when the heater was tantalum, indicating that the carbon had not come from an original impurity in the silicon powder.

One source of the carbon could have been volatile matter released from the graphite heater. This heater had been used about ten times at the time of the observations. A second source of carbon could have been a direct reaction between the quartz crucible and the graphite heater to form CO, or an indirect reaction involving a crucible-melt interaction and volatile SiO as an intermediate product. Such reactions should have developed SiC on the heater; and in fact a yellow powder did form on the inside of the graphite heater although its composition could not be determined.

Notes on the Plastic Critical Temperature In Strain-Induced Martensite Reactions

by C. Dean Starr

IT is well known that the martensite reaction can be induced to occur isothermally above the M_s temperature by plastic deformation of an alloy in its austenitic state, and also that as the test temperature is increased above the M_s temperature, plastic deformation under a given set of conditions merely causes additional slip with a corresponding tendency toward the formation of less martensite per unit of strain. Thus it appears that a maximum temperature exists above which martensite cannot be formed isothermally by plastic deformation. This temperature is commonly designated as the equilibrium temperature T_E .

Attempts to determine experimentally the equilibrium temperature have indicated that a critical temperature is observed, under a given set of conditions, above which martensite cannot be formed isothermally by plastic deformation. But the observation of a "so called" critical temperature, T_D , should not be confused with the equilibrium temperature, T_E .

In order to clarify this anomaly, true stress-strain curves were obtained for a series of type 304 stainless steel specimens (manufacturer's analysis, 0.08 pct C, 18 to 20 pct Cr, 8 to 10 pct Ni, balance Fe) over the temperature range 67° to 300°K.¹ Since martensite is magnetic, a quantitative measure of the amount of martensite that was produced by plastic deformation was obtained by determining the magnetic permeability as a function of strain. The results of these tests are given in Fig. 1. They appear to indicate that a plastic critical point does exist at about 240°K for the stainless steel under investigation here. But that 240°K is not the equilibrium temperature nor even a true plastic critical temperature can be seen from Fig. 2 wherein the permeability of the same material is shown to increase with cold rolling at 293°K.

Consequently the observation of a "so called" plastic critical temperature is dependent on the mode of deformation and has no theoretical significance.

Free Energy of Vaporization of Metals from 0° to 2000°C

by J. W. Evans

ONE of the most important and frequent calculations that the extractive metallurgist is called upon to make is that of the standard free energy change of a reaction (ΔF°). For many reactions of metallurgical interest, the lengthy arithmetical calculations have been eliminated by the use of free energy-temperature diagrams which have been constructed by Ellingham,¹ Richardson and Jeffes,² Kellogg,³ and Osborn⁴ (e.g., for oxides, sulphides, halides) from critical surveys of existing data. The speed and simplicity of making calculations with these graphs make them of great practical value and, this should be stressed, in the majority of cases no greater accuracy is obtained by the individual calculations from specific heat data, entropies, and heats of reaction.

With the increasing industrial application of vacuum methods to the winning of metals, notably at present magnesium and the alkaline earth metals, it is necessary to calculate low metal vapor pressures above reaction mixtures. The existing free energy diagrams usually give values where the solid and liquid metals are at unit activity. To obtain the free energy change associated with the reaction

it is customary to calculate this from either vapor pressure equations or from the appropriate free energy functions. This paper presents graphically the free energies of vaporization of a number of metals of economic importance which can be used in conjunction with other free energy diagrams. Certain metals have been excluded on the following grounds: titanium, tungsten, molybdenum, and platinum have very high heats of vaporization and

boiling points and the uncertainty of these values arising from difficulties of high temperature measurements makes free energy values of doubtful accuracy; the data for cobalt, vanadium, and zirconium are uncertain; finally, arsenic, antimony, and bismuth could not be conveniently included because of the presence of mixtures of polyatomic and monatomic vapors in the temperature range considered.

Free Energy Diagram

In Fig. 1, the standard free energies of vaporization per mol (ΔF°_T) have been plotted for the temperature range 0° to 2000°C for the reaction

The data have been obtained from the free energy functions $-(F-H_{298})/T$ for the solid, liquid, and gaseous elements and the heats of vaporization at 298°K, i.e., ΔH_{298} (vapor). The values of these functions have been taken without change from the recent critical survey by Brewer;⁵ the bulk of this data is from Kelley⁷ with adjustments in the light of more recent work. Values of the function $-(F-H_{298})/T$ at $T = 298^\circ, 500^\circ, 1000^\circ, 1500^\circ$, and 2000°K were employed. Where possible, a further independent value was obtained by using the boiling point, i.e., where $\Delta F^\circ_T = 0$. All calculations are based on the assumption that the metal vapors are monatomic and that the boiling points refer to those temperatures at which the partial pressure of the monatomic vapor above the metal is 760 mm. For the alkali metals, e.g., sodium, potassium, and lithium, diatomic gas molecules are present as minor species; details of these are discussed by Brewer.⁵

On the basis of the above values and allowing for the change in slope at the melting point, straight line graphs were constructed and extrapolated to 2000°C. The deviation from a straight line did not exceed ± 500 cal, which in all cases appears less than the probable error in the ΔF°_T values.

J. W. EVANS is associated with the Research Dept., International Nickel Co. of Canada, Copper Cliff, Ont., Canada.

Discussion on this paper, TP 3476D, may be sent, 2 copies, to AIME by July 1, 1953. Manuscript, Aug. 20, 1952; revised, Dec. 30, 1952. Los Angeles Meeting, February 1953.

Fig. 1—Free energies of vaporization of solid and liquid elements (ΔF°_T). Break in line occurs at melting point.

It will be noted that the slopes of the free energy lines are approximately the same; this slope corresponds to the temperature dependent term in the expression $\Delta F = \Delta H - T\Delta S$, i.e., the entropy change which, as it involves the simple physical change from liquid or solid to monatomic gas, would be approximately the same for all metals. The relative positions of the free energy lines and, hence, of the volatilities are determined by the heats of vaporization which clearly vary considerably from one metal

to another. For metals boiling below about 2000°K, the heats of vaporization are probably accurate to within one or two kilocalories per mol, but for the higher boiling metals, the heats of vaporization may be in error by ± 5 kcal or more.

Use of the Diagram

To those familiar with other free energy diagrams, the application of this present diagram will be fairly clear. One example, however, will be given by con-

sidering the thermal reduction of barium oxide with aluminum at 1500°K, i.e., 1227°C, and calculating the equilibrium barium gas pressure over this reaction.

The essential reaction is

From Osborn's data⁴

Adding reactions (a), (b), and (c) gives Eq. 1 for which

$$\Delta F^\circ_{1500} = +30,000 \text{ cal}$$

The equilibrium constant for Eq. 1 is given simply by $K = p_{\text{Ba}}^3$ if it is assumed that there is no interaction between barium and aluminum and that liquid aluminum, barium oxide, and alumina are at unit activities.

By definition, $\Delta F^\circ_T = -RT \ln K$

so that $\Delta F^\circ_T = -3RT \ln p_{\text{Ba}}$

By substituting $\Delta F^\circ_{1500} = +30,000 \text{ cal}$, $T = 1500^\circ\text{K}$, and $R = 1.98 \text{ cal}$, the calculated equilibrium vapor pressure of barium over Eq. 1 is about 27 mm Hg, which is a suitable pressure for the vacuum production of the metal commercially.

Vapor Pressures

Although the main purpose of the diagram is for free energy calculations, the diagram shows at a glance the relative volatilities over the whole temperature range, those with the greatest volatility having the lowest positive free energy change. The actual vapor pressure in atmospheres is related to

the free energy of vaporization by the formula

$$\Delta F^\circ_T = -RT \ln p$$

This may be conveniently written:

$$\log_{10} p \text{ (mm Hg)} = \frac{-\Delta F^\circ_T}{4.57 T} + 2.88 \quad [2]$$

Eq. 2 gives values for the vapor pressures which agree quite well (within 10 to 20 pct) with the three or four term equations usually quoted in the literature. For the more volatile metals, however, e.g., sodium and potassium, quite small errors in the ΔF°_T values of the order of only 500 cal give rise to substantial errors in the calculated vapor pressures. Where the ΔF°_T value is less than about +5000 cal, the calculated vapor pressure as obtained from Eq. 2 should be used with caution and the use of the more accurate multiterm equation is recommended.⁵

Simple Devices for Approximating Constant Stress During Tensile Creep Tests

by R. L. Fullman, R. P. Carreker, Jr., and J. C. Fisher

CREEP tests are usually constant load tests. As deformation occurs, the cross section of the specimen changes so as to maintain approximately constant volume. Until necking starts,

$$\frac{A}{A_0} \cong \frac{l_0}{l}$$

where A is the cross-sectional area, l is the specimen length, and the subscript 0 indicates initial values. Thus, during a tensile creep test under

constant load, the stress increases in proportion to the elongation.

$$S = \frac{F}{A} \cong \frac{F}{A_0} \frac{l}{l_0}$$

where S is the stress and F the load applied to the specimen.

R. L. FULLMAN, R. P. CARREKER, JR., and J. C. FISHER, Junior Members AIME, are associated with the Research Laboratory, General Electric Co., Schenectady.

TN 154E. Manuscript, Jan. 29, 1953.

Fig. 1—Schematic diagram of loading beam with center of gravity below fulcrum.

It has been repeatedly emphasized in the literature that, while constant load tests are convenient and may approximate some types of service conditions, constant stress tests are needed to gain an understanding of the nature of the deformation process. Constant load creep behavior can be calculated from constant stress data, but the reverse is much more difficult.

Andrade has described three methods of maintaining constant stress during creep tests,¹⁻³ none of which is as simple, from an equipment standpoint,

Fig. 2—Schematic diagram of loading beam with knife edges not collinear.

as the usual constant load test. Fisher and Carreker have described a method which maintains an approximately constant stress with relatively simple equipment.⁴ The method described below maintains a more nearly constant stress than that of Fisher and Carreker, while retaining the simplicity of the constant load test. The method requires only slight modification of most constant-load creep testing machines employing a beam loading arrangement. The mechanical advantage of the beam loading device is retained, permitting large stresses to be applied with relatively small weights.

Within the authors' knowledge, the method to be described originated in their joint discussion.⁵ It has been used successfully in their laboratory for several years and is now being used in other laboratories. Its simplicity and utility seem to warrant description.

If the fulcrum of a beam does not lie on a straight line containing the other knife-edges and the beam's center of gravity, the force transmitted by the beam is a function of the angle between the beam and the horizontal. When approximately horizontal, a simple beam having its fulcrum in a straight line contain-

ing the other knife-edges will maintain nearly constant stress in a tensile specimen if the center of gravity is located a distance r directly below the fulcrum, such that

$$r = \frac{P L_1 L_2}{W l_1} \quad [1]$$

where P is the applied load, L_1 and L_2 are the beam dimensions as shown in Fig. 1, W is the weight of the beam, and l_1 is the specimen length when the beam is horizontal. For optimum results, the initial angle of the beam should be such that it reaches a horizontal position when the specimen has attained half the maximum elongation of the test. Constant

Fig. 3—Stress change in tensile creep test.

stress is not maintained after the specimen starts to neck.

Existing creep machines employing a loading beam may be modified to make use of this method by a change in position of the beam center of gravity. With some equipment this change may be accomplished by the adjustment of existing counterweights. However, the method is somewhat inconvenient in that the position of the center of gravity or the beam weight must be changed for every change in load.

A more convenient application of the same principle may be obtained with a slight modification of the beam. In this case the center of gravity of the beam is placed at the fulcrum, but the fulcrum is not located on a straight line containing the other knife-

Fig. 4—Stress change in tensile creep test.

edges. Regardless of load, when the beam is approximately horizontal, a tensile specimen is deformed under nearly constant stress if

$$L_3 = \frac{L_1 L_2}{l_1} \quad [2]$$

where l_1 is the specimen length when the beam is horizontal, and L_1 , L_2 , and L_3 are the beam dimensions, as shown in Fig. 2. For optimum results, the initial angle of the beam should again be such that it reaches a horizontal position when the specimen is at half the maximum elongation of the test.

Figs. 3 and 4 show the variation of stress as a function of strain for maximum elongations of 1 and

The resolved shear stress, RSS, is given by the relationship⁹

$$\text{RSS} = \frac{F}{A} \sin \chi \cos \lambda$$

where χ is the angle between the tensile axis and the active slip plane and λ is the angle between the tensile axis and the active slip direction. During deformation by single slip, the crystal orientation and shape change in such a manner that

$$\frac{l}{l_0} = \frac{A_0}{A} = \frac{\sin \chi_0}{\sin \chi} = \frac{\sin \lambda_0}{\sin \lambda} \quad [4]$$

Combining this relationship with the geometry of the loading beam shown in Fig. 2, it is found that the resolved shear stress is maintained at approximately constant value if

$$L_3 = \frac{L_1 L_2}{l_1} \tan^2 \lambda_1 \quad [5]$$

where λ_1 is the value of λ at half the maximum strain of the test (i.e., the value of λ at $l = l_1$, as computed from Eq. 4). The resolved shear stress will then change during deformation in accordance with

$$\text{RSS} = \frac{P \sin \chi_0}{A_0 L_1} \left(L_2 - \frac{L_3 (l - l_1)}{\sqrt{L_1^2 - (l - l_1)^2}} \right) \left(\frac{\sqrt{l^2 - l_0^2 \sin^2 \lambda_0}}{l} \right) \quad [6]$$

Fig. 5 shows the influence of initial orientation of the crystal upon "percentage improvement" in constancy of resolved shear stress, defined by

$$\left(\frac{\Delta S_1 - \Delta S_2}{\Delta S_1} \right) \times 100 \text{ pct}$$

Here ΔS_1 is the maximum change in resolved shear stress during a constant load test and ΔS_2 is the maximum change in resolved shear stress during a test using a loading beam with dimensions that satisfy Eq. 5. The curves of Fig. 5 were computed for strains of 1 and 10 pct, and with $L_1 = L_2 = l_1$. Other dimensions would lead to similar results.

Conclusions

Proper choice of dimensions of a simple loading beam permit maintenance of very nearly constant stress during creep testing of polycrystalline materials or of nearly constant resolved shear stress during creep testing of single crystals.

Fig. 5—Influence of crystal orientation on constancy of resolved shear stress.

10 pct, if $L_1 = L_2 = L_3 = l_1$. The same result is obtained using a beam with a low center of gravity, if $W = P$ and $r = L_1 = L_2 = l_1$. The efficiency of the method can be expressed in terms of "percentage improvement" in constancy of applied stress, defined as

$$\left(\frac{\Delta S_1 - \Delta S_2}{\Delta S_1} \right) \times 100 \text{ pct}$$

Here ΔS_2 is the maximum stress change using the type of beam described and ΔS_1 is the maximum stress change with a constant load. For the case considered in Figs. 3 and 4, the percentages of improvement are: for 1 pct total elongation, 99.75 pct; and for 10 pct total elongation, 97.76 pct. A different choice of dimensions causes only a slight change in the efficiency of the method, provided Eq. 1 or Eq. 2 is satisfied. For any choice of dimensions which satisfies one of these equations,

$$S = \frac{Pl}{A_0 l_0} \left[\frac{L_2}{L_1} + \frac{L_2 (l_1 - l)}{l_1 \sqrt{L_1^2 - (l_1 - l)^2}} \right] \quad [3]$$

where l_0 and l are initial and other values of specimen length, and A_0 is the initial cross-sectional area of the specimen.

In tensile creep testing of single crystal specimens, it is desirable to maintain at a constant value the shear stress component on the active slip plane and in the active slip direction.* By suitable choice

* Hereafter this stress component will be called simply the "resolved shear stress."

of the beam dimensions, the loading beam just described can be used to maintain approximately constant resolved shear stress during creep of single crystals.

Electron Microscope Study of the Effect of Cold Work On the Subgrain Structure of Copper

by Laurence Delisle

This work represents the first step of an attempt to test the applicability of the electron microscope to the study of subgrain structures in copper. Observations on annealed and deformed single crystals and polycrystalline samples of copper are described.

IN the course of study of the structure of fine tungsten wires and tungsten rods with the electron microscope, well defined subgrain structures were observed. The size, size distribution, and orientation uniformity of the etch figures varied widely in different samples. Figs. 1 and 2, electron micrographs of a tungsten wire and of a tungsten rod, respectively, are illustrations of the difference in size and size distribution of the etch figures in different samples of the same metal. The observed differences, as pointed out in a previous paper,¹ appeared to be related to the heat and mechanical treatments of the samples. They were also consistent with the results reported in the literature on the mosaic structure of metals.² For that reason a program of research was initiated in an effort to obtain more systematic evidence of the possible relation of heat and mechanical treatments to the subgrain structure of metals as observed in the electron microscope. The purpose of this paper is to present observations made on the effect of cold work on the subgrain structure of copper.

Procedure

Starting Materials: Copper was the metal studied because it can be obtained in a high degree of purity, much information is available in the literature on its properties and its response to cold work and heat treatment, it shows no allotropic change, and it is sufficiently hard to be handled without great difficulty. Two groups of specimens were used: 1—single crystals cast from spectroscopically pure copper and 2—polycrystalline samples of oxygen-free high conductivity copper. Single crystals were studied because it was hoped that the elimination of a number of variables, such as grain boundaries, orientation differences, degree of purity, would simplify the problem and perhaps permit a better understanding of the phenomena that would be observed. The polycrystalline samples were designed to give a general picture of the changes considered.

The single crystals were made of copper which analyzed spectroscopically to better than 99.999 pct

L. DELISLE, Member AIME, formerly with Sylvania Electric Products Inc., is now associated with American Cyanamid Co., Stamford, Conn.

Cu. They were cast in vacuum, by the Bridgman method, in crucibles made of graphite with a maximum ash content of 0.06 pct. The mold design is shown in Fig. 3. It permitted casting crystals of the size and shape required for the experiments, so that the danger of introducing cold work in the original samples by cutting or other machining would be eliminated.

The polycrystalline samples were pieces, $\frac{3}{4}$ in. long, cut from a rod of oxygen-free high conductivity copper, $\frac{3}{8}$ in. in diameter. A flat surface, $\frac{1}{4}$ in. wide, was milled along the rods, polished, and etched. The samples were then annealed in vacuum at 850°C for 1 hr.

Polishing and Etching: Work previously done on tungsten,¹ polished mechanically and etched chemically,* had shown that: 1—the general appearance

* By "chemical etch" is meant attack of the surface of the specimen simply by flooding with or immersion into the etchant..

of the etch figures of a given sample was not altered by repeated polishings and etchings under similar conditions; 2—variations in the time of etching and the concentration of the etchant changed the definition of the etch figures, but did not alter their general size nor orientation distribution within the limits of observation. Further work confirmed the reproducibility of the subgrain structures observed in, 1—single crystals and polycrystalline samples of copper when polishing and etching were repeated under similar conditions, and 2—specimens of tungsten and polycrystalline copper when electrolytic polishing and etching were substituted for mechanical polishing and chemical etching, respectively. On the strength of these observations, it was felt that, if conditions of polishing and etching were kept constant, changes observed in the subgrain structure of a sample upon deformation and annealing would be attributable to such treatments. For that reason the conditions of polishing and etching were kept as constant as possible.

The single crystals were polished electrolytically in a bath of orthophosphoric acid in water, in the ratio of 1000 g of acid of density 1.75 g per cc to 1000 cc of solution, under a potential drop of 1.6 to 1.8 v. Electrolytic polishing was selected to prevent the formation of distorted metal in polishing. The same samples were etched by immersion in a 10 pct aque-

ous solution of $(\text{NH}_4)_2\text{S}_2\text{O}_8$. They required a long etching time, of the order of 1 hr. As was already observed in the case of tungsten, shorter etching time brought out poorly defined structures. As the etching time was increased, the structure gradually became clear. At such a point a steady state of solution was approached since no changes could be observed upon prolonging the etching time by as long as 1 hr. For that reason the sharpness of the struc-

tures, rather than the etching time, was used as a guide in etching the single crystals.

The polycrystalline samples were polished mechanically and etched for 5 min by immersion in a 10 pct aqueous solution of $(\text{NH}_4)_2\text{S}_2\text{O}_8$. Mechanical polishing was chosen because it permits a better control of the flatness of the surface. The polishing of the original machined samples was carried out on emery paper, through No. 40, and on silk and velvet wheels. The specimens were repolished after the 850°C anneal prior to deformation. Polishing in this case, as well as polishing subsequent to deformation, was done only on silk and velvet. In both cases, alternate final polishing on velvet and etching were repeated three times.

Deformation: The specimens were deformed in compression. The strains produced are given in Table I.

Examination with the Electron Microscope: Parlodion replicas, stripped dry from the surface of the specimens and shadow cast with manganese were the specimens observed in the electron microscope.

Prior to examination with the electron microscope, polishing and etching were controlled as far as possible with the light microscope. Within the limit of resolution of the light microscope, there was always agreement between the structures observed in the light and in the electron microscopes.

Observations on Single Crystals

Fig. 4 is representative of the structure of one of the single crystals as cast and etched. The structure consists of blocks with edges that are practically straight and faces that appear smooth. Fig. 5, a stereographic projection of the crystal, obtained from an X-ray back-reflection pattern by the Geringer method, shows that a $\{111\}$ plane is nearly parallel to the plane of Fig. 4, an orientation consistent with the three-fold symmetry exhibited by triangular areas between the blocks shown in the micrograph. Goniometric measurements indicated that etching took place on $\{110\}$ and $\{111\}$ faces.

Slip lines appear on the surface of the single crystals after deformation (Figs. 6, 8, and 9). The spacing and intensity of the slip lines that could be observed are not uniform. The closest visible spacing of the flow lines is of the order of 0.1 micron in the plane of the figure. A fine structure is also visible on the surface of some of the blocks. It shows a parallel arrangement along lines closer than 0.1 micron, suggestive of slip lines. Upon repolishing and etching the deformed single crystals, a block structure appears as in the cast samples. Within these larger blocks, however, the fine structure which was faintly visible before repolishing and etching is clearly brought out, Fig. 7. After deformation, the edges of the larger blocks are neither as straight nor as smooth as they appeared in the cast single crystals.

Observations on Polycrystalline Samples

Figs. 10 and 11 illustrate the structure after repolishing and etching, of the polycrystalline specimens annealed for 1 hr at 850°C. Within the grains a block structure appears, but the blocks are smaller than those observed in the single crystals. As will be shown further, by comparison with the subgrain structure in deformed samples, the subgrain blocks of the fully annealed specimens are uniform in size and orientation, and that uniformity extends from

Fig. 3—Graphite mold used to cast single crystals.

Fig. 4—Copper single crystal S1, as cast and etched. X4000. Area reduced approximately 50 pct for reproduction.

the center to the boundaries of the grains. In Fig. 12 the blocks within a grain are shown. As in the case of the cast single crystals, the blocks have edges that are nearly straight lines and the faces of most of them show no structural details.

As a result of deformation, slip lines appeared on the surface of the specimens. As is to be expected, the direction of the slip lines changes with the orientation of the grains, Figs. 13 and 14. In some grains, a multiplicity of slip lines indicates that several slip

Fig. 5—Stereographic projection of single crystal S1, as cast.

Fig. 7 (right)—Copper single crystal S1, deformed 20 pct. Repolished and etched after deformation. X4000. Area reduced approximately 50 pct for reproduction.

systems were operative, Fig. 15. The slip lines that can be seen within a grain are not evenly spaced, and are often crowded at grain boundaries, Fig. 16. The slip lines within a grain stop at the grain boundaries, Figs. 16 to 18, and slip lines in a different direction are sometimes visible in adjacent grains. In Figs. 16 and 17, one set of slip lines appear clearly in one of the grains and a second set, marked F, is faintly visible in the adjacent grain.

Upon repolishing and etching the polycrystalline samples, the slip lines disappear, but other evidences of deformation remain or become visible:

1—Some of the subgrain blocks are severely deformed, especially near grain boundaries, Figs. 19 and 20.

2—The uniformity of orientation of the subgrain blocks that was observed within most grains of the annealed material is destroyed by cold work, Figs. 21 to 23. Within grains, cold work seems to produce shifts in orientation. Such shifts manifest themselves by a change in the appearance of the subgrain blocks that look as if they were seen from different angles in different parts of the grains. The orientation shift is visible across Fig. 21 from the bottom left-hand corner to the top right-hand corner. A comparison of Figs. 10 and 21 brings out the difference in orientation uniformity before and after deformation, respectively. The change in orientation produced by cold work within individual grains is even more pronounced at grain boundaries, Fig. 22. A comparison of Figs. 22 and 18 suggests that the regions of a deformed grain that appear differently oriented after repolishing and etching may be bounded by glide planes.

3—A structure, much finer than the original blocks, of the order of 1000Å, appears, after cold working, at grain boundaries, on the surface of the blocks that had a smooth surface after annealing, and often in the angles formed by meeting subgrain blocks, Figs. 24 and 25. This fine structure is of the same order of size as the fine structure observed in deformed single crystals after electrolytic repolishing and etching, Fig. 7.

4—Some subgrain blocks broke completely into lamellae, Fig. 26. The subgrain blocks shown in the upper and in the lower parts of Fig. 26 are differently oriented within the same grain. They are separated by a region of blocks consisting of lamellae. The arrangement suggests that rotation of the lamellae of the intermediate blocks permits a fit between the two regions of differently oriented blocks of the same grain.

Discussion of Results

The electron micrographs presented in this paper add support to the existence of a complex subgrain structure in metals. The size of the smallest subgrain units observed in copper, like those previously observed in tungsten,¹ of the order of 1000Å, corresponds to that calculated by Bragg, Darwin, and James³ for the units of a mosaic structure from measurements of intensity of reflection of X-rays by crystals, by Wood⁴ for the limiting size of crystallites from line broadening, and by Born⁵ for a perfect lattice from quantum mechanics considerations. Such a dimension was used by Bragg³ to compute a satisfactory value for the elastic limit of strain of many metals. The size of the larger units of the subgrain structures observed in copper in this paper, and in tungsten previously,¹ is of the order of magnitude calculated by Taylor⁷ for the length through which a dislocation travels before being stopped by a surface of misfit. There seems to be therefore a size relationship between the subgrain structures observed with the electron microscope and the mosaic structures proposed by a number of authors.

On the other hand, there appears to be a relationship between mosaic structures and dislocations. According to Cottrell,⁸ it is "reasonable to suppose that the more macroscopic irregularities in crystals, e.g. mosaic structure and crystal fragmentation in the cold work state, are built up from assemblies of dislocations." If dislocations exist, the metal in the vicinity of a dislocation is stressed and for that reason its rate of etching should be faster than that of the stress-free material. If the blocks of the subgrain structure are considered as separated by arrays of dislocations, they should be brought out by etching. Read and Shockley⁹ explain that veining obtained by Lacombe¹⁰ is the result of etching that starts at dislocations. Once started, the etching proceeds on the planes that dissolve fastest. The same planes have slightly different orientations in different blocks and that difference accentuates the effect of etching. On a different scale of magnitude and disorientation, the phenomenon is similar to the etching of grains as ordinarily applied in metallography. The sizes of the subgrain blocks in the cast single crystals and in the annealed polycrystalline samples of copper studied in this paper agree with the calculations of Read and Shockley⁹ for small angles of misfit.

The number of dislocations should be a function of internal stresses and degree of purity.^{7, 8, 11-14} The single crystals used in these experiments were made of spectroscopically pure copper, they were cast in graphite of high purity, in vacuum, and they were cooled very slowly. They were therefore freer from impurities and internal stresses than the polycrystalline samples, made of commercial copper, and they should have a lower density of dislocations. The subgrain blocks of the cast single crystals are indeed much larger and therefore seem to represent a higher degree of perfection than those of the polycrystalline samples, Figs. 4 and 11.

The number of dislocations should be increased by cold work. The appearance of a fine structure within the blocks of the subgrain structure of the single crystals and the polycrystalline samples upon deformation, Figs. 7, 25, 26, could be explained by an increase in the number of dislocations. In Fig. 7, the alignment of the fine structure within the larger blocks suggests traces of slip planes. Such a structure was not visible in the cast crystals. It seems therefore that it was brought out by cold work. It

Fig. 25—Polycrystalline copper, deformed 22 pct. Repolished and etched after deformation. X10,000. Area reduced approximately 50 pct for reproduction.

is visible after etching, so that it is not a form of slip lines. It could be a structure that existed in the cast crystals,^{3, 5} but could not be resolved because the degree of disorientation of its units was too small. Deformation increased the degree of disorientation and permitted differential etching. It could also be recrystallized crystallites formed, according to Wood,⁴ when cold work on a slip system reaches a certain value. This fine structure has the characteristics of the strain markings reported by Burke and Barrett.¹⁵ If the evidence produced by Burke and Barrett that the strain markings are traces of slip planes rather than mechanical twins is accepted, the etching of such markings could be the result of the presence of the recrystallized crystallites proposed by Wood.

The individual subgrain blocks of the cold-worked samples, after repolishing and etching, often appear bent by the deformation, Figs. 19 and 20. Their size is comparable to the size they had before deformation, Figs. 12 and 20, and they can easily be visualized as the original blocks strained individually by different amounts in different regions of the grains. Such a mechanism seems possible only if the subgrain blocks revealed by etching are a real structure like the grains themselves.

It has been proposed by Burgers,¹⁶ Kochendorfer,¹⁷ and Laurent¹⁸ that dislocations during cold work are created at crystallite boundaries which produce notch effects. The stress field of the new dislocations counteracts the notch effect so that the production of new dislocations becomes more difficult and strain hardening occurs. In the single crystals, the more clearly visible flow lines often pass through the angles formed

Fig. 26—Polycrystalline copper, deformed 15 pct. Repolished and etched after deformation. X10,000. Area reduced approximately 50 pct for reproduction.

by meeting subgrain boundaries that could act as notches, Fig. 9. When several slip systems are operative, the dislocations connected with the first slip system should be an obstacle to the motion of the dislocations on a second slip system. In Fig. 15, the prominent, more widely spaced slip lines appear to have been stopped at places by a finer structure. In the single crystals, no grain and fewer subgrain boundaries hindered slip than in the polycrystalline samples. For that reason perhaps deformation proceeded in one slip system more extensively and slip lines in single crystals are often found to be closely spaced, Figs. 6 and 8. The latter figures are reminiscent, although on a different magnification scale, of electron micrographs of slip lines in aluminum published by Heidenreich and Shockley.¹⁹

On account of the glide in different directions, a slip plane becomes a grid of dislocations which, according to Cottrell,⁸ "constitutes a transition surface between two crystals rotated with respect to each other about an axis normal to the transition surface." The formation of such transition surfaces would explain the presence, upon deformation, of regions differently oriented within individual grains of the polycrystalline samples, Figs 21 to 23 and 26.

This paper described part of the results of an attempt to apply the electron microscope to the study of the changes in the subgrain structure of metals produced by cold work and recovery. Because its scope was wide and it represented a relatively new method of approach, the work was intended to be in the nature of a survey. For that reason no claim was made at conclusiveness and only possible relationships between accredited theories and the structures observed were indicated. It is hoped, however, that the possibility of the relationships pointed out will be considered sufficient to arouse interest in the potentialities of the electron microscope for the study of subgrain structures in metals.

Conclusions

1—A subgrain structure was observed, by means of the electron microscope, in single crystals of spectroscopically pure copper and in polycrystalline samples of oxygen-free high conductivity copper.

2—A study was undertaken in an effort to find out whether consistent changes would be produced by cold work and recovery in the subgrain structures observed in copper. Observations on the changes produced by cold work are reported.

3—The subgrain blocks observed in the cast and slowly cooled single crystals, as well as in the annealed polycrystalline samples, appear to have relatively straight edges and smooth surfaces.

4—The subgrain blocks observed in the cast single crystals are larger than those observed in the annealed polycrystalline samples.

5—Repolishing and etching of the deformed single crystals and polycrystalline samples brought out, within blocks that appear to correspond to the subgrain blocks observed prior to deformation, a finer structure, the size of which is of the order of 1000Å.

6—The degree of disorientation of the larger subgrain blocks within a single crystal or individual grains of the polycrystalline samples is increased by cold work. The larger subgrain blocks also appear individually deformed by cold work.

7—The larger and finer subgrain structures observed differ in size by an order of magnitude. They both correspond to crystallite dimensions reported in the literature on the basis of entirely different observations.

8—Comparable structures were previously observed in tungsten.

Martensite Habit Plane in Quenched Ti-Mn Alloys

by You Chao Liu and Harold Margolin

Investigation of martensite habit plane in water-quenched Ti-Mn alloys was carried out in the range of manganese contents between 4.35 and 5.25 pct. On the basis of 22 measurements, the poles were observed to fall into two groups, indicating the existence of two habit planes. The Miller indices of the poles close to these two groups were found to be $\langle 334 \rangle_{\beta}$ and $\langle 344 \rangle_{\beta}$.

TITANIUM has an allotropic transformation at $882.1^{\circ} \pm 0.5^{\circ}\text{C}^1$ by which the high temperature β (body-centered cubic) phase changes to α (hexagonal close-packed) phase. It is well known, as in the case of low carbon steel, that the unalloyed high temperature β phase cannot be retained no matter how rapid the cooling rate. However, the addition of alloying elements usually lowers the transformation temperature continuously and stabilizes the β phase to a temperature much lower than the allotropic transformation temperature in pure titanium. A typical example of this behavior is found with manganese-alloying of titanium.

Fig. 1 shows the titanium-rich Ti-Mn equilibrium diagram as established by Battelle Memorial Institute.² The addition of manganese lowers the β transus line and the eutectoid reaction takes place at 550°C , the eutectoid composition being 20 wt pct Mn. However, upon quenching to room temperature from the β field, the β phase can be completely retained with much less manganese, see Fig. 2. If the composition is less than that required to stabilize the β phase completely, a plate-like structure, similar to that of martensite in other alloy systems, appears as shown in Fig. 3. Much lower alloying content merely intensifies the amounts of these transformed structures, as shown in Fig. 4.

This paper presents the results of an investigation of the habit plane of these martensitic structures in Ti-Mn alloys.

Experimental Procedure

Investigation of the pole of a given platelet was made using the two-surface method of analysis.³ In

Y. C. LIU, Student Associate AIME, and H. MARGOLIN, Junior Member AIME, are Research Associates, Engineering Research Div., New York University, New York.

Discussion on this paper, TP 3498E, may be sent, 2 copies, to AIME by May 1, 1953. Manuscript, Sept. 15, 1952; revised, Jan. 27, 1953. Los Angeles Meeting, February 1953.

Fig. 1—Titanium-rich Ti-Mn equilibrium diagram. After Battelle Memorial Institute.

order that a given martensite trace on two surfaces be readily recognized both at low and high magnifications, it is desirable that only a small amount of martensite be present. From a review of the data obtained at Battelle Memorial Institute⁴ on quench hardening in Ti-Mn alloys and the results of Duwez⁵ on transformation in Ti-Mo alloys, it was decided that the most appropriate Ti-Mn composition for this study would be about 6 pct Mn. A group of alloys containing from 3 to 10 pct Mn was made to bracket this composition. The choice of the 6 pct alloy was apparently proper, since it was later learned that approximately 5.5 to 6 pct Mn is required to stabilize the β phase on water quenching.

Fig. 2—Ti-Mn alloy (8 pct Mn), water-quenched from 1200°C. Retained β . X75. Area reduced approximately 60 pct for reproduction.

Fig. 3—Typical martensitic structure in Ti-Mn alloys in the range of compositions investigated. X150. Area reduced approximately 60 pct for reproduction.

Fig. 4—Ti-Mn alloy (1 pct Mn) water-quenched from 1200°C. Transformed β . X100. Area reduced approximately 60 pct for reproduction.

Five different specimens with a nominal manganese content of 6 pct were finally used in this investigation. The actual compositions of these specimens varied from 4.35 to 5.25 pct Mn. In the case of the 4.35 pct specimen, transformation was so extensive that angular relations of selected platelets could be measured only by first taking photographs of two surfaces and then matching them. A specimen with a nominal manganese content of 3 pct produced Laue spots so broad as to make orientation determination impossible.

All specimens, $\frac{3}{8} \times \frac{3}{8} \times \frac{3}{4}$ in. in size, were heat-treated for 60 to 70 hr at 1200°C, in argon atmospheres to obtain grains of 0.8 to 1 cm in diameter, which proved to be adequate for this investigation.

Three polished surfaces* around the specimen

* The standard procedures for polishing and etching titanium and its alloys as employed at the New York University Metallurgical Laboratory⁶ have been followed.

corner were prepared in each specimen. This arrangement had the dual advantage that many traces

across the edges were available and that the angles between polished surfaces could be measured by manipulation of the stereographic projection.

The stereographic method used in the measurement of the angles between surfaces is described as follows: Fig. 5 shows three polished surfaces at corner O. Angles α , β , and γ were measured with the graduated circle on a metallograph. With surface A as the plane of the stereographic projection and corner O at the center, azimuthal angle α is located as shown in Fig. 6. The intersection of planes B and C, MN, is then represented in Fig. 6 as point M in the projection. The pole of surface C (which is defined by the edges OP and MN) is designated C and is located 90° from the great circle PMP'. Pole B is similarly located and represented. The three polished surfaces, A, B, and C in Fig. 5 are thus represented in Fig. 6 by their respective poles O, B, and C. The angles between the planes are equal to 180° minus the angle between the corresponding

Fig. 5—Schematic diagram of intersection of surface planes A, B, and C at specimen corner.

Fig. 6—Stereographic plot of Fig. 5.

NOTE. Angles indicated show distances from $\langle 111 \rangle$ pole.

Fig. 7—Location of poles of habit planes in a standard stereographic triangle.

poles; the latter angle can be measured along great circles in the projection.

The grain orientations were determined from Laue patterns by the back-reflection X-ray method.⁷ In the early stage of this work, difficulties were encountered due to the peculiar nature of the back-reflection X-ray photographs obtained. These showed high intensity spots, not related to any zones, and a scarcity of zones. The number of Laue spots was limited due to the fact that titanium has a very high absorption coefficient with respect to copper radiation. By using an exposure time of 18 hr with a current of 20 ma at 35 kv, sufficient spots for orientation determination were produced. The high in-

tensity spots could not be accounted for and were not considered. The orientations of two polished surfaces of a grain were checked against the value for the angle between these two planes as determined by the stereographic method described earlier. The difference between these two orientations, when brought into coincidence, was about one degree.

After it was learned that two habit planes occur in the present alloy system, it seemed appropriate to attempt to correlate the microstructure with habit plane. The fineness of the transformed structure in most cases ruled out the possibility of using the two-surface method; consequently a single-surface method was employed. The validity of the latter analysis then depended on the consistency of a large number of measurements.

In the single-surface analysis the orientation of the grain where the microstructure is to be studied, as shown in Fig. 8, is plotted on a stereographic projection. All permutations of the two habit planes, a

total of 12 each, are therefore plotted as the area corresponding to the original data obtained, Fig. 7. The trace normal of the investigated traces is then superimposed on the projection. If the habit plane of these traces corresponds to either of the two habit planes found, the trace normals must pass through one of these 24 areas.

Experimental Results and Discussion

Based on 22 measurements (two-surface) made on six grains in five crystals, the poles of the habit planes were found to fall distinctly into two groups, designated as α'_1 and α'_2 in Fig. 7, thus indicating the

Fig. 15—Another view of parallel martensitic platelets. X650. Area reduced approximately 60 pct for reproduction.

existence of two habit planes. The indices of these two habit planes were determined to be close to $\{334\}_\beta$ and $\{344\}_\beta$.

The martensite corresponding to the α'_1 habit occurs most frequently and appears as fine straight lines, Fig. 9. In more than 40 measurements on this type of structure, it was found that the trace normals, without exception, passed through the α'_1 region.

Figs. 10 and 11 show that the martensite platelet changes its direction of propagation quite readily. From 11 analyses, it has been found that the component parts of this type of structure always follow the α'_1 habit plane and that the poles of these two α'_1 planes always have an angular separation of 60° to 64° as measured on the stereographic projection.

A number of these interesting microstructures, in addition to those shown previously were also encountered during the present investigation. Some of these structures are shown in Figs. 9 to 15. Fig. 12 shows two parallel bands, one with smooth boundaries and the other jagged. These platelets generally are found together and the habit plane along which they occur is indicated. However, the submarkings within the bands cannot be accounted for on the basis of α'_1 or α'_2 planes of the matrix. This type of structure is the thickest observed, the estimated thickness being less than 0.001 in. Fig. 13 shows the same structure as Fig. 12. At the end of this coupled structure, the platelets tend to separate. The thickness of the platelets is reduced when they meet other martensitic transformation products.

Other types of substructure are often found in the martensite platelet. In one type, the substructure frequently extends into the untransformed matrix and in others it resembles twin formation in hexagonal close-packed metals. Fig. 9 shows dark-etching needles which are not confined to the main platelet, but other parallel markings which are confined are also visible. Fig. 10 shows "twins" within a martensite platelet.

The transformation structure is sometimes seen as a cluster of closely-separated parallel lines, as shown in Figs. 14 and 15. These markings can run either transverse or almost parallel to the direction of propagation.

In addition to the above, the following observations on the martensitic structure have also been made:

1—The mid-rib structure, characteristic of mar-

tensite structure in steel, does not occur in the Ti-Mn system.

2—Any boundary between the platelets and matrix corresponds, without exception, to one of the two habit planes found.

3—Submarkings within martensite cannot always be accounted for on the basis of α'_1 or α'_2 .

Summary

1—Two habit planes of martensite with Miller indices close to $\{334\}_\beta$ and $\{344\}_\beta$ were determined in the Ti-Mn system.

2—A variety of martensite microstructures have been found in the present alloy system. Many of these are quite different from the martensitic structures observed in steel, and in none of the structures is a mid-rib observed.

Technical Note

Observations on the Phase TiAg

by R. J. Van Thyne, W. Rostoker, and H. D. Kessler

THE existence of the phase TiAg has not been reported previously. Other investigators have denied the existence of compounds in the Ti-Ag system.^{1,2} However, phases of equi-atomic proportion have been reported by Raub, et al.¹ in the (similar) systems of titanium with gold and copper and zir-

conium with silver. Raub's work indicated that titanium and silver are immiscible in the liquid state. No evidence of this was found although a very wide melting range exists which makes the preparation of homogeneous alloys difficult. TiAg is apparently formed by a peritectic reaction between β

titanium and a silver-rich liquid phase.

The 68 pct Ag-Ti alloys were melted in a nonconsumable tungsten electrode arc-melting furnace. A detailed description of the melting techniques may be found elsewhere.³ Two alloys were prepared. Iodide titanium and a very pure grade of silver were used in the preparation of one alloy and sponge titanium was used for the other alloy. Fig. 1 illustrates the single phase microstructure of the alloy prepared with iodide titanium, annealed at 900°C for 24 hr.

The hardness of TiAg is quite low for an intermediate phase. A hardness value of 130 diamond pyramid hardness was obtained for both the higher and lower purity alloys. The alloy prepared with sponge titanium was cold-pressed 75 pct although edge cracking resulted.

The structure of the TiAg phase was determined by X-ray diffraction analysis. Powder patterns were taken on a 14 cm diam camera using filtered K α copper radiation. By trial it was found that the lines could be indexed on a tetragonal Hull-Davey type chart for a unit cell having an axial ratio just less than unity.

The relative intensities of the lines indicated a CuAu ordered face-centered tetragonal structure in which the atoms of one species are located at the

intensities were measured with aid of a Norelco type Geiger counter spectrometer.

The dimensions of the unit cell were computed by a least squares solution of equations for interplanar spacing of five high angle lines. The results were as follows: $a = 4.096$ kX, $c = 4.069$ kX, $c/a = 0.993$. Using these values, the interplanar spacings of each of the indexed lines were calculated and compared to the observed values. Table I summarizes the calculated and observed d values and relative intensities of the indexed lines.

Recrystallization of a Cold-Rolled Copper Single Crystal

by Y. C. Liu and W. R. Hibbard, Jr.

Based on pole figure data and microstructural observations, the recrystallization orientation found in a copper strip previously cold-rolled 99.5 pct from a single crystal with an initial (110) [112] orientation may be described as: a 30° rotation, clockwise and counterclockwise, about octahedral poles of the cold-rolled texture such that all four poles function at a low annealing temperature (400°C) and only three of them function at high temperatures (500° to 1050°C). The relative intensity of deformation stresses on various slip planes can be correlated with the choice of poles affecting the rotations found in the recrystallized orientations.

ROTATIONAL reorientation about the poles of densely packed crystallographic planes is an important characteristic of secondary recrystallization¹⁻⁴ in face-centered cubic metals. Some evidence has also been interpreted to show that such a rotational relationship also exists in the primary recrystallization process.⁵ In an investigation of the crystallographic relationships in the recrystallization process, several aspects of the experimental procedure should be considered. With cold-rolled polycrystalline metal as the initial material, pole figure analysis leaves many ambiguities as to whether or not simple indices can be assigned to adequately represent its orientation. The rolling texture does not consist of a single texture. Minor deformation textures are usually present. In all cases, twin textures are present. The presence of both minor and twin deformation textures influences the recrystallization texture. In order to study the recrystallization mechanism, a more precise knowledge of the history of the material before recrystallization is necessary. Tensile deformation of a single crystal usually produces residual stresses which are concentrated at slip bands. Since the exact nature and orientation of these potential nuclei sites cannot be experimentally evaluated, the tensile deformation of a single crystal was not considered adequate.

From the work done by Barrett and Steadman⁶ on copper, it appeared that cold rolling of a single-crystal specimen with an initial (110) [112] orientation would yield a specimen which fulfills the

conditions required for the present investigation, namely a highly preferred single rolling texture with relatively homogeneous stress distribution. By investigating the recrystallization texture of this material, additional details of reorientation during recrystallization might be obtained. The purpose of this paper is to describe such an investigation.

Experimental Procedure

Copper used in the present investigation was cathode sheet with a purity of 99.94 to 99.97 pct. A copper single-crystal specimen, 1.15x0.8720x0.5322 in. (thickness) was cut from a cylindrical crystal which was grown in a Bridgman furnace.⁷ The cutting was accomplished on a horizontal milling machine operated at a very slow speed to obtain a (110) plane in the rolling plane and a [112] direction in the rolling direction. The disturbed surface was removed by electrolytic polishing in dilute orthophosphoric acid (H_3PO_4) with a specific gravity of 1.14, and a current density of about 1 to 2 amp per sq cm. A 3-min polishing was needed to eliminate the disturbed surface causing Debye-Scherrer rings and a 45-min polish produced a surface which yielded sharp rounded Laue spots. It was estimated that about 1/16 in. of metal was removed from the original cut surface. The final orientation of this specimen before rolling was about 2° from the (110) plane in the rolling plane with a [112] direction aligned in the rolling direction. It is possible that a small amount of strain was still present in the cube despite the fact that the Laue spots seemed very sharp. It is doubtful, however, that this would be an important factor after a subsequent rolling reduction of 99.5 pct.

This copper specimen was rolled on a laboratory rolling mill with two highly polished rolls 3 3/8 in. in diam in the following manner: 0.010 in. per pass to 50 pct reduction, 0.005 in. to 70 pct, 0.002 in. to 85 pct and, finally, 0.001 in. per pass to a 99.5 pct reduction.

Specimens, about 1 in. sq with the rolling edges intact, were cut from the rolled strip by the electrolytic method previously described, after the strip

Discussion on this paper, TP 3527E, may be sent, 2 copies, to AIME by July 1, 1953. Manuscript, Sept. 10, 1952; revision, Feb. 10, 1953. Los Angeles Meeting, February 1953.

This paper represents part of a thesis by Y. C. Liu submitted in partial fulfillment of requirements for the degree of Doctor of Engineering to the Faculty of the Engineering School of Yale University, May 1952.

was covered with electroplater's masking tape, with the exception of a thin slit at the place where it was desired to cut the specimen.

Annealing was carried out in an electrically heated liquid metal or salt bath where possible. Each specimen was dusted with alumina powder and placed between two copper sheets 0.020 in. thick. The assembled sandwich was wrapped with several layers of copper foil 0.002 in. thick. A thermocouple was fastened to each envelope, so that the exact temperature of the envelope could be measured. In all cases, the temperature variation during annealing was controlled within $\pm 5^\circ\text{C}$. In the annealing of the specimen at 1050°C in an air furnace, it was found that the furnace temperature dropped to 980°C upon the introduction of the specimen. A 30-min (1800-sec) reheating period was required prior to the 300 sec at 1050°C .

Cold-rolling textures were determined by ordinary pole figure construction^{8,9} with the help of the glancing X-ray method¹⁰ to complete the center portion of the pole figure. An integrating camera¹¹ was employed in the construction of the recrystallization pole figures because of the large grain size. Since all the recrystallization pole figures were asymmetrical about either the rolling direction or transverse direction, the ordinary basic chart for the construction of pole figures was modified to cover all four quadrants.

Metallographic specimens were electrolytically polished and etched according to the ASTM method for copper and its alloys.¹² Tracings of microstructures were made after each heat treatment and the percentage of recrystallization was determined by averaging 15 measurements of the number of squares of cross-section graph paper encompassed.

Results and Discussion

A single-crystal specimen of copper, with a (110) plane parallel to the rolling plane, was rolled in a [112] direction lying in the rolling direction. The resulting pole figure, Fig. 1, shows that even after 99.5 pct reduction in thickness, the rolled strip still retained essentially its original orientation with about 8° of scatter. The cold-rolled texture has no twin component. This experiment confirms earlier work done under the similar conditions in copper⁶ and in brass¹³ and recently in a Cu-Si alloy.¹⁴ Since the specimen, after 99.5 pct reduction, was less than 0.003 in. thick, it was not expected that there would be a distinct difference of cold-rolled texture on the specimen surface and in the interior of the specimen as had been reported.¹⁵⁻¹⁶

Table I. Recrystallization Measured in Annealed Specimens

Annealing Temperature, $^\circ\text{C}$	Annealing Time	Percentage of Recrystallization
200	One week	Less than 1 pct
300	300 sec	None observed
300	1000 sec	First trace of recrystallization visible at 400X

400	1000 sec	68.0
500	30 sec	78.1
500	100 sec	88.2
500	300 sec	95 (estimated)
700	300 sec	100
900	300 sec	100
980-1050	1800 sec	100
1050	300 sec	100

Fig 1—Octahedral pole figure of cold-rolled copper strip after 99.5 pct reduction in thickness.

A series of specimens from the same rolled strip was annealed at temperatures ranging from 200° to 1050°C . The percentage of recrystallization measured in the annealed specimens is listed in Table I. These data show that the range of annealing temperatures and times includes the entire recrystallization process.

The recrystallization texture of all annealed specimens was plotted in the form of conventional octahedral pole figures in Figs. 2 to 10. In general, successive pole figures are quite consistent within the experimental error and possess one center of symmetry, namely a 180° rotation about the center of the figure. Specimens annealed at lower temperatures yielded pole figures containing more high intensity areas than those annealed at higher temperatures. In the latter case, however, these areas were more compact and of somewhat higher intensity. The range and the complexity of the results make it impossible to describe the recrystallization textures adequately by means of simple Miller indices. The predominately cubic recrystallization texture of polycrystalline copper strip was not found in the present specimens.

By careful analysis of the pole figures, a relationship was found between the orientation of the recrystallized grains and the deformation texture. If the deformation orientation is rotated about each one of its octahedral poles, 30° both clockwise and counterclockwise, the resulting ideal orientations were found to best fit the high intensity areas of the pole figures of recrystallized specimens. The theoretical orientations obtained from the rotations described above are plotted in Fig. 11 and these orientations are also plotted as circles (both open and solid) in the individual pole figures in Figs. 4 to 10. The results fit the data very well, especially for the specimens annealed at lower temperatures. The 30° type rotation about the (111) type pole is similar to prior results on a rolled copper single crystal¹⁷ recrystallized at 450°C , although the latter was not rolled in the critical (110) [112] orientation.

The selection of the 30° rotation, both clockwise and counterclockwise, was made on the basis of the fact that the resulting ideal orientations were then

Fig. 2—Octahedral pole figure of copper specimen annealed one week at 200°C.

Fig. 3—Octahedral pole figure of copper specimen annealed 300 sec at 300°C.

Fig. 4—Octahedral pole figure of copper specimen annealed 100 sec at 400°C.

Fig. 5—Octahedral pole figure of copper specimen annealed 300 sec at 400°C.

located for the most part at the center of these intense areas. Actually, any combination of pairs of opposite rotations in the range of 26° to 34° , totaling 60° would be suitable. Opposite rotations totaling 60° about an octahedral pole will generate a twin orientation across the plane of this octahedral pole in face-centered cubic metals. It is possible that orientations, other than those resulting from the rotations suggested, will also fit the data, but it is doubtful that these orientations will satisfy all of the intense areas and also have a simple relationship among themselves.

For annealing temperature at and above 500°C , differences between the ideal orientations and the experimental data occur as shown in Figs. 7 to 10. Two relatively intense areas near the periphery at 1 and 7 o'clock have not been accounted for and six (solid) circles of the theoretical orientations result-

ing from rotations about octahedral pole IV, are not in intense areas. The failure of the recrystallized grains to include an orientation relationship about octahedral pole IV at higher annealing temperature might be interpreted as the result of either: 1—the recrystallized grains resulting from the rotational reorientation about pole IV being absorbed during grain growth, or 2—the rotational reorientation process not functioning with respect to octahedral pole IV.

The first alternative, that grains related to pole IV are actively generated at the start of recrystallization but are absorbed by other growing grains, requires that this absorption occur between 400°C (Fig. 6) and 500°C (Fig. 7) as indicated by the loss of intensity about the orientations with the solid circles. Such a selective absorption from the four equivalent groups of orientations is considered im-

Fig. 6—Octahedral pole figure of copper specimen annealed 1000 sec at 400°C.

Fig. 7—Octahedral pole figure of copper specimen annealed 300 sec at 500°C.

Fig. 8—Octahedral pole figure of copper specimen annealed 300 sec at 700°C.

Fig. 9—Octahedral pole figure of copper specimen annealed 300 sec at 900°C.

probable. Therefore, it is suggested that the difference between the recrystallization textures for high and low temperatures is the activation of nuclei related to pole IV at low temperatures, but not at high temperatures.

The second possibility mentioned above may be considered in terms of deformation stresses on the octahedral slip planes based on single-crystal behavior during cold-rolling and correlated with subsequent recrystallization. Maddin, Mathewson, and Hibbard, working on brass,¹⁸ and Chen and Mathewson, working on aluminum,¹⁹ have reported that the orientations of recrystallized grains may be related to the orientation of the deformed crystals by rotations about poles of the active slip planes.

Fig. 12 shows the positions of $[111]$ poles and $[110]$ directions for the starting orientation, $(110)[112]$. The equation for resolved shear stress is

written as

$$S = \frac{F}{A} \cos \phi \cos \lambda \quad [1]$$

where ϕ is the angle between stress axis and normal of the slip plane and λ is the angle between stress axis and slip direction.

If slip takes place during cold rolling in accordance with the resolved shear stress considerations based on plane parallel compression, it is clear that the plane IV, which is perpendicular to the rolling plane and parallel to rolling direction, has a resolved shear stress equal to zero. Theoretically, this slip plane should not operate during cold rolling and at most it would be expected that this slip plane functions least in comparison with the other three octahedral planes. If the factor of stresses on an octahedral plane is assumed to influence recrystal-

Fig. 10—Octahedral pole figure of copper specimen annealed 1800 sec at 980° to 1050°C and 300 sec at 1050°C.

Fig. 11—Ideal orientations resulting from the proposed recrystallization rotations.

lization, then it follows that the low stresses on plane IV rendered the plane least potent in the recrystallization process. The stresses on plane IV, then, may be sufficiently large to cause plane IV to contribute to recrystallization below 500°C, but yet small enough so that they are relieved at temperatures above 400°C rapidly enough and to the extent that plane IV does not contribute to recrystallization at these temperatures.*

* This interpretation is consistent with the results of Maddin, Mathewson and Hibbard¹⁸ and Chen and Mathewson¹⁹ that, after annealing at high temperatures (800° and 600°C), new orientations could be related only to the poles of those planes which were active during deformation. These findings suggest a significant dependence of the activation of nuclei on stress configuration and a competitive relation between the rate of stress relief and the nucleation frequency at the annealing temperature. It has been reported that the nucleation frequency is dependent upon both the amount of strain and stress relief.^{20,21} These factors also affect the incubation time for recrystallization, and therefore the time available for stress relief. Thus, it is more probable that stress relief can occur during the incubation period for potential nuclei in regions of small strain and low residual stress such as along plane IV, provided the temperature is sufficiently high.

Fig. 12—The positions of octahedral poles and dodecahedral directions in a (110) [112] orientation.

Fig. 10 is the pole figure plotted for the specimen annealed 1800 sec at 980° to 1050°C and 300 sec at 1050°C. The area around [111] poles I and II are less intense than the area around [111] pole III. If this phenomenon is dependent on a stress factor, then it would be expected that the stresses are higher on plane III than on planes I and II.

Hibbard and Yen²² suggested that the stable end orientation of cold-rolled polycrystalline strips of face-centered cubic metals is (110) [112]. The slip systems that operate in a grain rolled in this orientation are systems I-2 and II-1 in Fig. 12. The combination of slip on these two operative slip systems produces a "flow" phenomenon, such that a grain rolled in (110) [112] orientation can experience further cold rolling without changing its orientation.

The role which the (111) plane III plays during cold rolling is complex. According to theory,²² owing to the unfavorable orientation of slip directions in

Fig. 22—Specimen annealed 300 sec at 700°C. Rolling direction is vertical. X500. Area reduced approximately 60 pct for reproduction.

this plane, III, with respect to the rolling direction, this slip plane should not operate during cold rolling without a change in orientation. The location of the slip plane causes the $\cos \phi$ value in Eq. 1 to become large with respect to the tensile component in the rolling direction due to cold rolling. In that way, the plane itself would be subjected to large stresses built up during deformation, but the unfavorable position of the slip directions with respect to flow restricts slip. Under such conditions a high stress is built up on plane III. Slip on planes I and II may relieve a portion of this stress, but that remaining on plane III is probably higher than that on planes I and II subsequent to their yielding. The role of slip plane III in this situation might be analogous to that of the cross slip plane in tensile specimens. As reported by Maddin, Mathewson, and Hibbard in brass¹⁸ and Chen and Mathewson in aluminum single crystals,¹⁹ the subsequent anneal of those specimens yielded the recrystallized grains which were more frequently related crystallographically to the poles of cross slip planes than to the poles of primary and conjugate slip planes.

A schematic representation of the comparative

amount of stress on the individual [111] planes of the deformation texture is shown in Fig. 13. The relatively high stresses existing on the [111] plane, III, is believed to be responsible for the observation that the most intense areas of the pole figures of recrystallized specimens may be related to rotations about the pole of this plane III.

The presence of intense areas around the solid triangles in Figs. 8 and 9 may lead to the conclusion that some of the recrystallized grains may have an orientation similar to the deformed matrix, since, at these annealing temperatures, it has been found that these specimens have experienced full recrystallization. The analysis of the pole figure intensities at the four [111] poles of the deformed structure (solid triangles) is not a true way of estimating the number of recrystallized grains with this orientation. Since each of these four poles acts individually, in a crystallographic sense, as a center of rotation to develop the recrystallized orientations, these four [111] poles are therefore each associated with other orientations of newly formed grains and are not necessarily combined into a single orientation. It is not known whether (110) [112] type grains, if they

Fig. 23—Stereographic analysis of Fig. 22.

exist, are the result of the rotational reorientation or "recrystallization in situ."

As indicated by Table I, the temperature range used in this experiment covers the range of the recrystallization process. By comparing Figs. 4, 5, and 6, it is clearly seen that no significant change in the recrystallization texture has been produced by time during isothermal annealing. Also, in general the annealing temperature has a rather small effect on the orientation of the recrystallized grains, provided annealing has been carried out above 500°C.

Microscopically, the recrystallization process in the present specimen is entirely different from what has been reported previously for the polycrystalline copper strip. The specimen was very reluctant to recrystallize. No sign of recrystallization was observed after an anneal of 300 sec at 300°C. On increasing the annealing time to 1000 sec some recrystallization was observed. Annealed for a week at 200°C, the amount of recrystallization was estimated as less than 1 pct.

At a very early stage of recrystallization, a few large grains were found together with a small number of fine grains. In no case was a grain of circular outline observed. No attempt was made to measure the rates of nucleation and growth in the present investigation.

The characteristic feature of the microstructure of the recrystallized grains in the present specimens is the abundance of annealing twins. Figs. 14 to 18 show the typical structure of these specimens. It is interesting that the textures are not a twinned type in the usual sense (i.e., not twinned across planes perpendicular to the rolling plane and containing the rolling direction or the transverse direction), although they possess two-fold rotational symmetry.

Preferential growth of the recrystallized grains takes place during the recrystallization process. Figs. 19 and 20 show that the grain boundaries of the recrystallized grains are very jagged and extend finger-like into the deformed matrix. Even the microstructure of the specimen which has been annealed 300 sec at 900°C, Fig. 21, shows grain boundaries which clearly indicate that the equilibrium shape of grains has not yet been attained.

In testing the validity of the results obtained on the basis of the pole figure data, the orientation of certain grains could be determined by means of three twin families. It was expected that these orientations so independently determined should be among the eight orientations produced by the recrystallization rotations described above. All the measurements made both on the micrographs and under metallographic inspection conformed to this expectation. One of the micrographs, Fig. 22, is, therefore, reproduced here with the stereographic analysis.[†]

[†] In the stereographic analysis, the solid lines represent the traces of the twins in the corresponding micrograph, and the dotted lines represent the locus of octahedral poles corresponding in turn to these solid lines. The solid triangles represent the [111] poles of one of the eight equivalent orientations suggested by the recrystallization mechanism.

From both the pole figure and microstructure studies, it may be concluded that the recrystallization reorientations suggested in the present investigation are in good agreement with experimental observations.

Summary

1—A single-crystal specimen of cathode copper was cut with the (110) plane parallel to the rolling plane and was rolled in a [112] direction. After cold rolling, a pole figure showed that the final strip retained its original orientation with a spread of about 8° after a 99.5 pct reduction in thickness.

2—Specimens electrolytically cut from the cold-rolled strip were annealed at temperatures and times ranging from the initial stages of recrystallization to just below the melting point of copper.

3—Qualitatively, increasing the annealing temperature causes little change in the final recrystallization texture, provided the annealing temperature is above 500°C in the present specimen. Annealing time had no measurable effect on the orientations of the recrystallized grains.

4—The recrystallization reorientation found in the present investigation can be described as: 30° rotation clockwise and counterclockwise, about each of four [111] poles of the deformation texture at low annealing temperatures (up to 400°C) and only three at higher annealing temperatures (500°C and above).

5—The distribution of deformation stresses is considered an important factor which influences recrystallization reorientations.

Acknowledgment

The authors would like to express their gratitude to William Tragart of Yale University, Edmund C. Burke of the Dow Chemical Co., and Harold Margolin of the Research Div., New York University for their helpful reading of the manuscript. The copper was supplied by the Raritan Copper Works, Perth Amboy, N. J., through the courtesy of Stanislaus Skrowronski.

Technical Note

On the Distribution of Sodium in Modified Al-Si Alloys

by A. B. Michael and M. B. Bever

THE structure of cast Al-Si alloys is altered profoundly by modifying agents. Sodium, in particular, reduces the size of the silicon particles in the eutectic and tends to change their shapes from plates to nearly rounded grains. This refinement is accompanied by a shift of the eutectic to higher silicon concentrations and lower temperatures. Similar effects can be attained by rapid solidification.

Hypotheses advanced to explain modification have involved the formation of a ternary eutectic,¹ the removal of oxides by fluxing,² and even a presumed allotropic transformation of silicon. Other hypotheses assume that the modifying agent causes an envelopment of the silicon particles by the aluminum-rich solid solution, but attribute this envelopment to different mechanisms. According to various explanations, the growth of the silicon particles is obstructed by an immiscible sodium-rich liquid,³ an adsorbed layer of sodium,⁴ or a ternary compound;⁵ this obstruction has been conceived as purely mechanical or as a colloidal action.⁶ It has also been proposed that sodium reduces the surface tension on the Al-Si interface, thus permitting the aluminum-rich solid to grow faster and to envelop the silicon particles.⁷ Still other hypotheses stress undercooling and the attendant change in the rate of nucleation of silicon, but fail to ascribe any definite function to the sodium addition.⁸⁻¹⁰

Procedure

High-purity alloys of aluminum and 3 or 7 pct Si were treated with modifying agents containing radioactive sodium tracers. The experiments were intended to investigate the partition of sodium between the primary aluminum-rich solution and the

eutectic, and, if possible, to determine whether sodium is concentrated in or around the silicon particles in the eutectic. Radioactive sodium fluoride, alone or mixed with stable sodium chloride, was allowed to react with the alloy for 5 min immediately before solidification in the crucible. Modification could not be attained with additions of less than the equivalent of approximately 0.1 pct Na. Some alloys were not completely modified, but comparison of the structures of treated and untreated specimens indicated a very considerable reduction in particle size of the silicon in all of the former. A treated alloy is shown in Fig. 1.

Radioactive sodium fluoride was prepared by bombardment with deuterons having an energy of 14 mev. This bombardment (totaling, for example, 6 microampere-hours in one run) produced radioactive Na^{24} (half-life 14.8 hr) by the reaction $_{11}\text{Na}^{23}(\text{d}, \text{p})_{11}\text{Na}^{24}$. The radioisotopes of fluorine also produced have short half-lives and were not detected. A half-life determination by counting confirmed that the measured activity was due to Na^{24} .

The distribution of the sodium in the solidified alloys was determined by an autoradiographic technique by which a suitable stripping film is attached to a very thin metallographic specimen. After exposure and development, this emulsion remains superimposed on the specimen and may be examined microscopically or photographed by reflected light. The emulsion of the autoradiograph can be correlated directly with the underlying surface by simple adjustment in focus. The details of this technique have been described elsewhere.¹¹

Results

Fig. 2 is a micrograph of the autoradiographic emulsion ("autoradiograph") lying directly above the area of eutectic in Fig. 1. Fig. 3 shows a similar autoradiograph of a region consisting of primary solid solution. The small black dots (tracks) in these autoradiographs are developed grains in the emul-

sion due to radiations emitted by disintegrating sodium atoms. The uniform dark areas are eutectic in the underlying metal surface, which was not in focus when the micrographs of the emulsions were made. Blanks were processed simultaneously with the radioactive specimens. Their autoradiographs showed a negligible number of tracks.

The β tracks in the autoradiographs could not be traced to either of the two phases in the eutectic. The partition of sodium between the primary constituent and the eutectic, however, was determined by counting the number of developed grains in the emulsion above unit areas of these structures. These counts were made on ground glass images and on micrographs focused at a constant depth below the surface of the emulsion to eliminate possible variations with depth in the number of developed grains. Only the centers of large areas of eutectic or primary constituent were examined to avoid any effects due to cross radiation, which would occur near the boundaries between these structures. Since the thickness of the specimens was only about 20 microns, interference from subsurface layers was not appreciable.

In counts made on several specimens of the 3 and 7 pct Si alloys the number of developed grains was

found to be approximately equal above regions of eutectic and of primary solid solution. This observation shows that sodium was not concentrated preferentially in the eutectic. It can be inferred as probable that in the eutectic sodium was associated with the aluminum-rich solid solution rather than with the silicon particles. In that case, the ratio of sodium to aluminum was higher for the eutectic than for the primary constituent, but this may be attributed to the lower temperature at which the eutectic solidifies from the residual liquid.

The finding that sodium was approximately equally distributed between the eutectic and the primary constituent and the inference that it probably was associated with the secondary aluminum-rich solid solution in the eutectic does not directly lead to a choice between the various hypotheses of modification. In particular, it can be argued that only a small fraction of the total sodium present may be effective in inducing modification and that the location and action of this effective portion is still not known. On the other hand, the observations reported here invalidate any hypothesis of modification which im-

plies a close association of the bulk of the sodium with the silicon.

Rate of Formation of Isothermal Martensite in Fe-Ni-Mn Alloy

by R. E. Cech and J. H. Hollomon

KURDJUMOV and Maksimova reported experiments with manganese steels and high carbon steels¹ and with an Fe-Ni-Mn alloy² in which martensite was formed isothermally over a range of temperatures. They found in some cases that martensite formation could be suppressed by rapid quenching to liquid nitrogen temperature. From their microstructural observations of martensite formed isothermally, they concluded that the rate controlling step is nucleation rather than growth.

Kulin and Cohen,³ in an attempt to reproduce these experiments, found that with a steel having the same composition as that reported by Kurdjumov and Maksimova, the transformation to martensite was essentially complete above the temperature range of Kurdjumov and Maksimova's isotherms. The possible reasons for this disagreement were not considered.

Recent papers by Das Gupta and Lement⁴ and Kulin and Speich⁵ report the formation of isothermal martensite in a high chromium steel and in an Fe-Cr-Ni alloy, but neither paper can be considered a verification of the original Kurdjumov and Maksimova results. Further, in neither case were the authors able to suppress the formation of martensite entirely.

Because of the important bearing the Kurdjumov and Maksimova results have to an understanding of the mechanism of martensite reactions it was felt that an experimental investigation directly concerned with checking the validity of their results was in order. This paper describes the results obtained on the isothermal transformation over the temperature range from -79° to -196°C of an alloy of iron, nickel, and manganese.

Experimental Apparatus

A 15 lb heat of an alloy containing 73.3 pct Fe, 23.0 pct Ni, and 3.7 pct Mn was melted by induction and cast under argon. The ingot was forged to 1-in. bar and a portion rolled to $1/16 \times 1\frac{1}{2}$ -in. strip. This strip was pack-homogenized 300 hr at 1100° in a helium-filled sealed iron tube. The composition after homogenization was 73.2 pct Fe, 22.94 pct Ni, 3.73 pct Mn, 0.05 pct C, and 0.015 pct N. The strips were cut to $\frac{1}{2}$ -in. width for dilatometer and metallographic specimens. Only the center portion of the $1\frac{1}{2}$ -in. strip was used in the present investigation.

The dilatometer employed was similar in design to one described by Flinn, Cook, and Fellows.⁶ A concentric fused quartz rod and tube assembly with hooks for holding the specimen was mounted so as to transmit the specimen dilation to a $1/10,000$ in.,

$1/10$ in. travel dial gage. The dilatometer proper was mounted by means of extension arms to a counterweighted sliding member on a vertical standard. This method of mounting permitted rapid transfer of the dilatometer from the austenitizing furnace to the quenching bath and low temperature chamber. A small electrical vibrator on the dilatometer kept frictional effects of the quartz members at a minimum.

The austenitizing unit was a vertical, molybdenum-wound, hydrogen atmosphere furnace maintained at a constant temperature $\pm 3^{\circ}\text{C}$ by means of constant power input. A 12-in. stainless steel jacketed copper liner having $\frac{1}{2}$ -in. wall thickness acted to equalize the temperature in the hot zone of the furnace. This liner, closed at the bottom end and open at the top to permit entrance of the dilatometer and specimen, was kept filled with dry nitrogen gas. A chromel-alumel thermocouple was placed inside the tube to determine the temperature. The 4-in. dilatometer specimens in the chamber varied less than $\frac{1}{2}^{\circ}$ across the specimen length except for a $1\frac{1}{2}^{\circ}$ drop at the end nearest the open end of the furnace.

The low temperature isothermal holding bath was a double Dewar arrangement similar to one described by Turnbull.⁷ The outer bath was filled with a refrigerant at a temperature lower than the desired holding temperature. The inner bath was filled with Freon "11" or "12" or a mixture of both, depending upon the holding temperature. This inner bath which tended to be cooled by the outer bath was kept at a constant temperature by introducing a small amount of heat with a manually controlled electric heater. Stirring was accomplished by bubbling dry air through the bath. A Leeds and Northrup type K potentiometer was used to measure the inner bath temperature as indicated by a five element copper-constantan thermopile. The bath temperature was maintained within $\pm 0.2^{\circ}\text{C}$ of the desired temperature by occasionally adjusting the heater current so as to keep the Leeds and Northrup galvanometer at zero deflection with a constant setting of the potentiometer. Isothermal tests were usually continued for 300 to 400 min and another reading made at approximately 1000 min if the bath, unattended overnight, had not deviated in temperature more than 5°C . Transformation curves are drawn dashed (Fig. 1) through the time region where temperature was not controlled precisely.

Experimental Procedure

Dilatometer specimens of $1/2 \times 1/16$ -in. strip were cut to $4\frac{1}{2}$ -in. length and holes were drilled for the quartz hooks with proper spacing to give a 4-in. measured length. A thermocouple consisting of 0.012-in. diameter chromel and alumel wires was spot welded to the specimen and threaded between the dilatometer rods to binding posts near the dial

Fig. 1—Isotherms for martensite formation in Fe-Ni-Mn alloy.

gage. A new thermocouple was used for each specimen.

Specimens were austenitized 2 hr at 940°C, quenched into icewater and held 10 sec, rinsed in alcohol near 0°C for 20 sec, and quenched into the Freon holding vessel. A self-balancing photoelectric potentiometer connecting the specimen thermocouple produced a temperature time record of the quench. Dial gage readings of the specimen length were begun as the specimen approached the holding temperature and continued as a function of time of holding. The specimen length passed through a minimum as its temperature approached that of the bath and martensite forming isothermally caused a volume increase equal to that of thermal contraction. The time at which this minimum occurred was taken to be the initial time at transformation temperature, and the specimen length at this time to be the initial length. The martensite formed from isothermal-type transformation during the slow approach to the holding temperature was determined separately as is described later.

Isothermal transformation runs were made at -79°, -90°, -100°, -120°, -125°, -128°, -140°, -150°, -159°, and -196°C. Each isotherm was repeated three times, in some cases using three different specimens and in others with the same specimen re-austenitized. Isotherms were reproducible within 2 pct except at -79°, -90°, and -196°C, where reproducibility was 3 to 4 pct. The austenite mean grain diameter of 0.325 mm resulting from the high temperature homogenization did not change even after repeated transformation and re-austenitization of the specimen.

The amount of martensite present at the time the specimen had reached the holding temperature was determined by quenching separate specimens, in the same manner as the dilation specimens, up-quenching into warm water at the time corresponding to the initial dilation reading and examining metallographically. The amount of martensite formed on cooling a number of specimens in this manner is listed in Table I. The scatter was quite large both between specimens and in different areas of the same specimen. Specimens cooled to -196°C were entirely free of martensite with the exception of a few regions containing a fraction of 1 pct of mar-

tensite. However, a significant amount (2 to 5 pct) could be formed by warming slowly from -196°C in air instead of up-quenching.

The major factor influencing the amount of martensite in the specimens listed in Table I is believed to be the period of time in cooling and reheating during which the specimen temperature was in the region of rapid transformation. For specimens cooled to -100° to -159°C this time was about 15 to 30 sec depending upon bath composition, bath temperature, and surface condition of specimen. For specimens quenched in liquid nitrogen the time was 3 sec.

The data in terms of specimen length change as a function of time at constant temperature were converted to the percentage of martensite formed as a function of time by up-quenching a specimen at the end of the test and determining through metallographic lineal analysis the total amount of martensite present. Each specimen was sectioned at two points and the martensite determined on each section. The amount of martensite formed on cooling to the temperature of holding, Table I, was subtracted from the total to obtain the isothermal martensite percentage. The total isothermal length change of that specimen was divided into the isothermal martensite percentage in order to determine the percentage of martensite formed per unit length expansion. This calibration was applied to all dilatometer specimens having reproducible dilation curves. A distribution curve of the number of specimens vs martensite-length change calibration value

Table I: Martensite Formed During Approach to the Holding Temperature

Transformation Temperature, °C	Initial Martensite, Pct
-79	0
-90	0
-100	0.5-1.5
-111	1.0-2.0
-120	1.0-3.0
-125	1.0-3.0
-128	1.0-3.0
-140	1.0-3.0
-150	1.0-3.0
-159	1.0-3.0
-196	0 -0.5

was determined. The curve was normal indicating a randomness of errors. The value of the mean was found to be 7.4 pct martensite per 0.001 in. per in. linear isothermal expansion. The probable error of the mean was ± 0.1 pct martensite corresponding to an error in calibration of $1\frac{1}{3}$ pct. The change in calibration factor due to variation of specific volume change with temperature was calculated from the thermal expansion in the region of -70°C of a fully austenitic specimen and a specimen containing 45 pct martensite. It was found that the error introduced in the temperature region of the isotherms was much less than the $1\frac{1}{3}$ pct error of the mean. Further, it was found that the addition of this correction factor to the dilation calibration did not result in a reduction of the calculated error. Therefore, it was felt unnecessary to include this additional correction factor.

A surface layer of higher martensite content was formed to a depth of 0.002 to 0.005 in. during isothermal transformation. In making lineal analyses to determine martensite content of specimens, this surface layer was avoided. Visual observation of specimens that had been transformed different lengths of time indicated that the martensite content in the surface layer increased with holding time in about the same manner as the interior. It is believed that this surface effect results from depletion of manganese or carbon at the surface.

The isothermal transformation curves are plotted in Fig. 1. Time was plotted as $t + 1$ min to permit the inclusion of the first minute of isothermal transformation on a log plot. The curves were cross-plotted to obtain the TTT curve of Fig. 2.

Isothermal transformation rates were also determined for two temperatures, -111° and -159°C , by a metallographic method. Specimens were transformed for various lengths of time, quenched to room temperature, and prepared for metallographic examination. The quantity of martensite present in each specimen was determined by lineal analysis. Only one cross section per metallographic specimen was used in the lineal analysis determination of martensite in this case. The scatter of individual martensite determinations was about 1 to 2 pct which was within the estimated uncertainty of the lineal analysis measurements.

Micrographs from a number of specimens of one

series are shown in Fig. 3. The metallographically determined points are plotted in Fig. 4 along with the corresponding dilatometrically determined curves. In both cases, only the percentage of martensite formed isothermally is plotted. Though the agreement at -111°C is good, five of the eight metallographically determined points at -159°C are high, although only two are at greater variance with the dilatometric curve than the expected limit of error of a linear analysis measurement. Postulations regarding the discrepancy are of a speculative nature. One possibility is that the bath temperature was incorrectly adjusted for subzero treatment of metallographic specimens. Another is that, since metallographic specimens were taken from a different portion of the ingot, the composition may have varied slightly from that of the dilatometer specimens. At the time of the investigation it was felt that the deviation was not sufficiently greater than the expected errors to warrant repeating the experiment.

The effect of interruption of isothermal transformation at -111°C upon further transformation at -111°C was investigated. It was found that a small amount of martensite formed on heating from the holding temperature. After aging 5 min at room temperature and recooling, transformation continued at a much decreased rate. These results are in agreement with the findings of Das Gupta and Lement⁴ on a high chromium steel.

A preliminary experiment to determine if a delayed quench resulted in stabilization was performed by delaying the quench at 20°C for 2 and 30 sec before subcooling to a transformation temperature of -111°C . The results indicated that the magnitude of stabilization in these times is less than the scatter of individual isotherms. However, a similar quenching treatment resulted in stabilization of the isothermal transformation at -128°C . Specimens were held in a water bath at 20°C for 2 sec, for 30 sec, and for 24 hr before subcooling. The specimens given the 30-sec delay and the 24-hr delay in quenching transformed at a slower rate for the first few minutes of isothermal transformation than did the specimen given the 2-sec delay. Transformation rates were about equal after this time. The difference in initial transformation rates corresponded to 2 pct martensite for the specimen subjected to a

30-sec delay and 4 pct martensite for the specimen subjected to a 24-hr delay in quenching. The term "stabilization" refers, in this report, to the above mentioned slowing of isothermal transformation.

These experiments may indicate that stabilization occurs only below a certain critical temperature. However, it is felt that these data are not yet extensive enough to completely substantiate such a conclusion. A more thorough investigation of stabilization in this and other materials is in progress.

In the opinion of the authors the dilatometric data and room temperature observation of microstructures of transformed specimens provide insufficient evidence to resolve with certainty the question of whether isothermal martensite is produced by slow growth of pre-existing nuclei or by thermal nucleation followed by rapid growth to full size martensite platelets. To determine directly the speed of growth of martensite platelets a high-low temperature microscope stage was designed and built. The construction and operation of this stage are described elsewhere.⁸ It was possible to reproduce the time-temperature history of dilatometric specimens very closely in this stage.

Specimens were cut to size, metallographically polished, and austenitized in an evacuated quartz tube for 2 hr at 940°C . After cooling to room temperature, specimens were mounted in the microscope stage, austenitized 10 min at 940°C , quenched directly to a subzero temperature and held isothermally. The subzero holding temperatures elected for successive experiments were -125° and -190°C . The specimen surface was observed at these tem-

peratures for periods ranging from 10 to 30 min both visually and with the aid of a 16 mm motion picture camera set to a speed of 24 frames per sec.

It was found by visual observation, and examination of motion picture frames, that individual martensite platelets began growing at different times and grew to full size in less than $1/24$ sec. In some cases a martensite platelet would grow larger after initial growth by a series of discontinuous increments. These observations confirm the findings of Kurdjumov and Maksimova^{1,2} of Das Gupta and Lement,⁴ and of Machlin and Cohen⁶ based on the room temperature examination of microstructures of transformed specimens.

The results of this investigation support, at least qualitatively, the experimental findings of Kurdjumov and Maksimova on the isothermal transformation in a 23 pct Ni, 3.4 pct Mn alloy. There are significant differences, however. Kurdjumov and Maksimova's temperature of maximum transformation rate (-47°C) differs by 80°C from the temperature of maximum transformation rate (-128°C) found in this investigation. The greater manganese content, 0.3 pct, of the present alloy would be expected to lower the martensite formation temperature 10° to 20° at most (for athermal transformation). It seems unlikely that its effect on isothermal transformation would be great enough to account for the difference. It is more likely that the composition of Kurdjumov and Maksimova's alloy was at variance with that stated in his publication.

An error in the composition of the alloy used by Kurdjumov and Maksimova in a previous investiga-

Fig. 4—Comparison of dilatometrically and metallographically determined isotherms.

tion may also have been responsible for Kulin and Cohen's failure to reproduce the experiment on the 6.0 pct Mn, 0.6 pct C steel.

Kurdjumov and Maksimova report an M_s temperature (-17°C) for the Fe-Ni-Mn alloy, thereby inferring that athermal martensite forms to some extent. However, the cooling rate of 10°C per min used in its determination was sufficiently slow to allow detectable quantities of isothermal martensite to form at the reported M_s .

Kurdjumov and Maksimova do not state whether or not an athermal component was found on rapidly quenching to the lowest possible temperature. In the present investigation it was shown that the formation of martensite could be entirely suppressed by rapidly quenching small specimens in liquid nitrogen to temperatures as low as -196°C . It can then be concluded that athermal transformation is not a necessary prerequisite to subsequent isothermal transformation.

The stabilizing effect of an interruption of holding in the temperature region of isothermal transformation is believed to be due to the same factors causing partial stabilization by an interruption of quench prior to subcooling. In the latter case no martensite was present during the stabilizing treatment. It thus appears that the suggestion of Das Gupta and Lement (that stabilization is caused by the removal of an accelerating effect imposed on the steel by partial transformation) does not apply for the alloy used in this investigation. It is more likely that the diffusion of carbon plays a role in this stabilization phenomenon.

The isothermal transformation data reported in this investigation have been interpreted by Fisher¹⁰ as thermal nucleation of martensite followed by rapid growth.

Summary

The following characteristics of the austenite-martensite transformation have been observed in an Fe, 23 pct Ni, 3.7 pct Mn alloy:

1—Isothermal formation of martensite occurs in the temperature range from -79° to -196°C . The rate of formation increases with decreasing temperature to a maximum at -128°C and decreases with further lowering of temperature.

2—The formation of martensite can be suppressed

completely in this alloy by rapid quenching below room temperature.

3—Partial stabilization can be brought about by aging at room temperature, either prior to subcooling or after some isothermal transformation.

4—Isothermal transformation proceeds by delayed formation of martensite nuclei followed by rapid growth to full size martensite platelets.

Acknowledgments

The authors are pleased to acknowledge the assistance of D. Turnbull in many helpful discussions and criticism and of Mrs. LaVerne Danko for performing many of the lineal analyses required in the present investigation.

Identification of the Precipitate Accompanying 885°F Embrittlement in Chromium Steels

by R. M. Fisher, E. J. Dulis, and K. G. Carroll

IT is well known that ferritic steels containing more than 15 pct Cr when subjected to temperatures in the range of 700° to 1000°F exhibit increasing hardness and decreasing ductility. The phenomenon has been widely termed the "885°F embrittlement," after the temperature of most marked effect.^{1,2} In view of the excellent review articles available in the literature³⁻⁸ only a brief account of experimentally established facts need be given here.

The extent of changes in physical characteristics during embrittlement depends on chromium concentration and time at temperature, higher alloy content and longer time both promoting more rapid and extensive changes. In a 27 pct Cr steel, changes in impact strength and in angle of fracture in bending can be detected after only a 1 hr exposure at 885°F; after 50 hr this steel becomes quite brittle. Hardness increases slowly with time during thousands of hours exposure and may attain a maximum hardness number twice as large as that of the unexposed steel.

Microstructural changes accompanying embrittlement have been described as an initial widening of grain boundaries followed by eventual darkening of ferrite grains. Embrittled steels etch more readily, e.g., the weight loss of a 27 pct Cr steel in acid solution may occur at a rate one hundred fold greater following exposure at 885°F. Marked changes which accompany embrittlement have been observed in electrical resistivity, specific gravity, and magnetic coercive force. Changes in physical properties may be readily removed by heating at temperatures above the embrittling range, such as a treatment at 1100°F for 1 hr.

It has frequently been noted that the 885°F embrittlement suggests precipitation on a submicroscopic scale of a chromium-rich constituent, the nature of which has not been revealed by X-ray diffraction. Progressive broadening of the body-centered cubic diffraction lines during embrittlement has been observed,⁶ and recent observations by Lena and Hawkes⁷ upon single crystals have shown early asterism in X-ray photographs, disappearing within an hour at 900°F. Many workers have ascribed⁸⁻¹³ the phenomenon to a precipitation of σ phase (FeCr), which is known to cause embrittling effects at temperatures much higher than 885°F. Two general observations, however, suggest that σ precipitation cannot be responsible for the 885°F phenomenon: 1—prior cold work greatly enhances σ formation, whereas it scarcely affects the 885°F embrittlement,

and 2—the presence of an alloying element such as nickel or manganese may have an effect on the 885°F embrittlement which is opposed to its effect upon σ formation.

The slight enhancement of σ formation and 885°F embrittlement observed in the presence of elements with strong carbide and nitride forming tendencies² is probably a consequence of lessened chromium depletion of the matrix. The bar graph in Fig. 1 shows a typical example, taken from two 27 pct Cr steels used in this work, of the hardness after exposure for 10,000 hr at 900°, 1050°, and 1200°F. Steel A (0.03 pct C, 3.13 pct Mn) showed marked hardening at 900° and 1200°F, whereas steel B (0.12 pct C, 0.63 pct Mn) exhibited only the 900°F hardening. The σ phase was found in steel A at the higher temperatures but not in steel B. Presumably σ formation is enhanced by the low-carbon and high-manganese concentrations in A.¹⁴ Thus there are two distinctly different hardening phenomena present which cannot both be ascribed to σ precipitation without invoking a transition phase possessing remarkable properties.

Materials

A number of chromium steels exposed for long periods (5000 to 34,000 hr) at 900°F, as well as unexposed samples of one of the steels, were available for this investigation. Table I gives the chemical compositions and aging treatments of these steels. In addition to these steels exposed in the elevated temperature test furnaces of the National Tube Division, a number of high-chromium steels were heated for short periods in small laboratory air furnaces and lead baths. Supplementing these commercial steels, a sample of high-purity (0.018 pct C, 0.002 pct N) 28 pct Cr iron, exposed 1000 hr at 887°F, was furnished by the Union Carbide and Carbon Corp. In addition, an alloy of iron and chromium of high purity containing 46 pct Cr was used. This

material, made by vacuum fusion, was obtained from the National Research Corp., Cambridge, Mass.

Optical Microscope Examination of Embrittled Steels

The micrographs of Fig. 2 illustrate the phenomenon of 885°F embrittlement in a 27 pct Cr steel. Ferrite grains in the unexposed steel (sample C) are clear, the outlined or dark etching constituents being chromium carbide and nitride. After an exposure of 34,000 hr at 900°F (sample E), the ferrite appears darkened by a precipitate which is too fine to be resolved by the optical microscope, and a veining or subgrain structure can be seen in the darkened ferrite. This precipitate dissolves rapidly in the ferrite matrix upon heating to 1200°F, as shown in Fig. 2c, leaving the microstructure much as it appeared in the unexposed steel of Fig. 2a.

These changes in microstructure are reflected in hardness of 198, 369, and 202 diamond pyramid hardness for the specimens of Figs. 2a, 2b, and 2c, respectively. These results indicate that a definite microstructural change accompanies the hardness increase during the long time exposure at 900°F, and that the embrittled steel quickly returns to its initial hardness and to a structure similar to the initial microstructure upon heating at 1200°F. The hardness of sample E (369 DPH) was not significantly different from that of sample D (373 DPH).

Electron Microscope Examination

Fig. 3 shows electron micrographs of the samples shown in Fig. 2. These are photographs of uranium-shadowcast plastic replicas stripped from the polished and etched surfaces of the steel before and after exposure at 34,000 hr at 900°F. This one-step plastic replica technique results in negative replicas, in that unetched projections on the original surface appear as depressions in the micrographs. The smooth, unetched regions in both figures correspond to the carbides and nitrides in the steel. The rough background in Fig. 3b indicates the presence of a precipitate in the ferrite matrix which is too fine to be resolved by this replica technique. This is analogous to the ferrite darkening shown in the optical micrograph of Fig. 2b; however, the vein structure was not observed.

A new "Extraction Replica" technique that is applicable to these samples has recently been devel-

Fig. 1—Effect of aging temperature on hardness of two 27 pct Cr steels after 10,000 hr exposure.

oped at this Laboratory. This technique will soon be reported elsewhere and will be described here only briefly. It has been found possible to free from the metal matrix the precipitate particles that are partially embedded in the replica plastic by etching the sample a second time through the plastic. The replica contains the actual precipitate particles, thus avoiding the loss in resolution inherent in any replica technique. By suitable manipulation of the electron beam, it is possible to select areas of the replica containing separated particles for diffraction patterns by transmission. An alcoholic solution of picric and HCl acids (grain size reagent) has been found most effective for the stripping technique on chromium steels, although solutions of bromine or iodine in alcohol may also be used.

Fig. 4 shows particles of the precipitate which are responsible for the ferrite roughening of Fig. 3b. Fig. 4a is an extraction replica of sample D (10,000 hr, 900°F) and Fig. 4b shows the precipitate in sample E (34,000 hr, 900°F). The precipitate particles seem to be spherical as they always appear circular in the micrographs and never rodlike as would disks on edge. The particles are quite uniform in size, varying from about 150 to 300Å but averaging 200 in Fig. 4a and 230 in Fig. 4b. Resolution of the micrographs here limits accuracy to about $\pm 30\text{\AA}$.

Fig. 2—Microstructures of steel C (27 pct Cr). Picric-HCl etch. X1000. Area reduced approximately 50 pct for reproduction.

Fig. 3 — Uranium shadowed replicas of 27 pct Cr steel. HCl-picric etch. X15,000. Area reduced approximately 50 pct for reproduction.

a (upper) — Before exposure.

b (lower) — 34,000 hr at 900°F.

Fig. 4a and b also illustrates quantitatively the increase in numbers of particles from 10,000 to 34,000 hr exposure although there is little change in particle size. Some clustering of particles in Fig. 4b results from slightly over etching the second time so that some previously unexposed particles that are not fixed to the plastic are free to cluster together. This is difficult to avoid with such small precipitate particles.

Transmission electron diffraction from the same area of the replica shown in Fig. 4b gives the pattern, reproduced in Fig. 5, of a simple body-centered cubic phase of lattice parameter similar to that of iron or chromium. Because pure iron and pure chromium differ in lattice parameter by only 0.6 pct, it is not possible to distinguish between these two elements, or their solid solution, by means of electron diffraction alone. It is interesting to note the evidence of preferred orientation in the diffraction pattern of Fig. 5, which indicates that the replica technique removed the particles from the steel without disturbing their orientation. The six-fold symmetry in the inmost $\{110\}$ ring suggests that the precipitate formed with its $\{110\}$ planes coincident with the six $\{110\}$ planes of the ferrite matrix.

Electron diffraction examination by means of the same replica technique described above showed the presence of the body-centered cubic precipitate in sample F (17 pct Cr, 5000 hr, 900°F), sample G (16 pct Cr, 10,000 hr), and sample H (15 pct Cr, 10,000 hr). The patterns from these samples were considerably weaker than from the 27 pct Cr steels and the particle diameter of the precipitate was about 125Å in H to 175Å in F. No body-centered cubic pattern was obtained from sample I (14 pct Cr, 10,000 hr) and no precipitate particles were observed.

Weak patterns were obtained for the precipitate in samples of the 46 pct Cr alloy after 700 hr at 900°,

950°, and 1000°F. The strongest pattern was obtained from the 950°F sample and the $\{200\}$ diffraction line was unusually weak in all these cases.

The patterns from the high-purity Union Carbide and Carbon specimens (28 pct Cr, 1000 hr, 887°F, hardness 275 DPH) were rather weak and here also the $\{200\}$ line was relatively weaker than in the 10,000 hr samples. The particles were too small to be clearly resolved by the electron microscope and from this fact, and from measurements of line broadening effects, they are estimated to be less than 50Å in diameter.

No precipitate could be observed in extraction replicas of the sample of Fig. 2c (sample E reheated 1 hr at 1200°F) nor was a body-centered cubic electron diffraction pattern obtained from these replicas. A strong body-centered cubic pattern was obtained from an extraction replica of another small piece of sample E (27 pct Cr, 34,000 hr, 900°F) reheated ¼ hr at 1100°F. The precipitate particles were about 120Å in diameter and the hardness of this sample was 239 DPH.

X-Ray Examination

X-ray examination of the etched surface of sample C (before) and samples D and E (after embrittlement) showed no new diffraction lines but only a slight broadening of the original body-centered cubic ferrite lines after exposure. Fig. 6 shows the diffraction pattern of the residue obtained by dissolving a small sample of embrittled steel (sample E, 34,000 hr, 900°F) in grain size reagent (HCl-picric acid in alcohol). This pattern was obtained on a Philips 90° spectrometer with filtered chromium radiation. It shows the presence of Cr_7N and Cr_{23}C_6 as minor constituents, along with strong $\{110\}$ diffraction from a body-centered cubic lattice. This material showed no evidence of ferromagnetism when tested with a small hand magnet and in a magnetic susceptibility balance. Similar patterns were obtained from the surface of the solid

Fig. 4 — Extraction replicas of 27 pct Cr steels. X60,000. Area reduced approximately 50 pct for reproduction.

a (upper) — 10,000 hr at 900°F.

b (lower) — 34,000 hr at 900°F.

steel specimen after it was etched deeply, except that the {110} diffraction line was masked by the ferrite {110} line.

X-ray fluorescence was used to measure the relative Fe-Cr composition of the extract from sample E. A copper target tube was used for excitation, and a sodium chloride crystal as monochromator. For calibration purposes a pure alloy of iron and chromium containing 46 pct Cr was used. Repeated observations on this and other similar extracted materials from samples D and E yielded a result of approximately 85 pct Cr-15 pct Fe. This, of course, includes the chromium in the carbide and nitride as well as the precipitate.

The lattice parameter of the body-centered cubic constituent was measured in the spectrometer modified for back reflection, by measuring the diffraction angle of the {211} reflection, under chromium radiation, in comparison with that from spectroscopically pure iron ($a = 2.8665\text{\AA}$). Values were obtained for extracts from steels D and E after 10,000 and 34,000 hr exposures at 900°F of 2.877 and 2.878 \AA , respectively. Precision of these measurements is limited by particle broadening which prevented accurate resolution of the α doublet. The lattice parameter measurements would imply a chromium content of about 70 pct;¹⁵ however, influence of residual elements as well as particle broadening prevents accurate estimates of composition from these measurements.

X-ray examination of the etched surfaces of samples F and G (heavily cold-worked before exposure at 900°F) showed the presence of σ phase (FeCr) as well as Cr_2N and Cr_{23}C_6 . The strength of the electron diffraction pattern for the precipitate from these samples indicated that extraction of it for X-ray examination was not feasible. The σ phase was found in sample A after aging at 1050° and 1200°F but not in steels B, D, or E after aging at these temperatures. X-ray observations of σ phase in these samples verifies previously reported identification by metallographic means.^{12, 13}

A small amount of residue extracted from the high-purity 28 pct Cr sample was examined by X-ray diffraction. No diffraction lines were obtained from the specimen due probably to the extremely small size of the particles. X-ray fluorescence analysis of the residue gave a chromium to iron ratio of about ten or twelve to one.

Chemical Composition of Extracted Materials

Table II lists the results of chemical analyses of the residues obtained by dissolving embrittled samples in the grain size reagent used previously as an etchant. Samples which were first investigated (D and E) were simply left in the etching solution until considerable residue had collected on the surfaces of the specimens and then removed from the solution and dried. After drying, the surfaces were carefully brushed and the residue collected. To obtain quantitative data on the amount of residue in an embrittled steel, samples A and B were crushed in a mortar, weighed, dissolved in grain size reagent, and the residue washed by decanting in alcohol. After washing, the residue was collected, dried, and weighed. The amount of residue available for analysis varied between 0.2 and 0.5 g. Rather more reliance is placed upon the chemical analysis of steels A and B because more extract was available for analysis and because of improved techniques in handling.

From Table II it is seen that the Cr-Fe ratio agrees

Fig. 5—Electron diffraction pattern of area shown in Fig. 4b.

moderately well with the ratio determined by X-ray fluorescence analysis. While the reported nitrogen contents of the extracted materials from samples A and B are quite consistent with the yield factors and the nitrogen contents of the initial steels (Table I), the carbon values are several times larger than would be expected from the yield factors and the carbon content of the steels. It is probable that these discrepancies are due to organic contamination both from the etchant and from etching products not removed during washing. The estimated carbon contents listed in Table II were obtained by multiplying the original carbon content of the steels by the concentration factor in the extraction. This assumes that all the carbon in the steels was combined as carbide and was recovered in the extraction.

Since the X-ray results showed that the extract consists only of Cr_{23}C_6 , Cr_2N , and the body-centered cubic precipitate, it is possible to compute the relative proportions of these three phases in the extract, and also the composition of the precipitate. Table III lists the results of these computations, using the nitrogen values from the analyses and the estimated

Fig. 6—X-ray diffraction pattern of residue extracted from 27 pct Cr steel exposed 10,000 hr at 900°F .

* Estimated from nitrogen values of steel and extract.

values for carbon. Agreement among the samples in the composition of the body-centered cubic precipitate is quite good except for sample D which was the smallest sample and yielded the bare minimum of residue that could be analyzed.

The proportions by weight of the constituents in the extracts can be converted into weight proportions in the embrittled steels by using the yield values of Table II. Table IV shows the results of calculating the composition of the steels in this way. Values in parentheses are the values for the carbide and nitride that would be expected from the carbon and nitrogen contents of the steels. The values computed from the analyses of the extract are all higher than the values computed from the steel analyses. This error, whatever its origin, tends to decrease both the apparent chromium content of the body-centered cubic precipitate and the apparent amount of precipitate formed. The chromium content of the remaining ferrite is computed by subtracting the chromium combined as nitride, carbide, and body-centered cubic precipitate from the original steel chromium analysis and calculating its weight percent in the remaining ferrite matrix.

Magnetic Measurements

Preliminary qualitative observations with a small Alnico permanent magnet revealed that the extractions from embrittled steels were either nonmagnetic, or only weakly magnetic. Quantitative measurements were made in a magnetic susceptibility balance. In this instrument a magnetizing field of about 400 oersteds was provided, and the tractive force in an inhomogeneous field was measured on a standard chemical balance. Extracts from specimens D and E revealed no detectable ferromagnetism; those from A and B gave tractive forces equal to about 10 pct of the specimen weights. For comparison, under identical conditions, steel C gave a tractive force equal to twice its weight. Electron diffraction examination of one of the magnetic residues indicated the presence of magnetite, which may account for the slight ferromagnetism.

Small pieces of embrittled steels D and E were investigated over a range of temperatures up to 670°C (1238°F) in the same instrument. No evidence was found for any Curie temperature, other than the principal one at 600° ± 5°C (1112° ± 9°F) which, according to Adcock,¹⁵ is appropriate to a 27 pct chromium ferrite. No hysteresis effects were found upon heating above and cooling below the Curie

temperature; hence no chromium depletion of the ferrite was evidenced. In view of other findings this may be ascribed to the rapidity of solution of the precipitate in the ferrite matrix above 475°C (887°F), because during the course of the measurements at least 30 min was spent in increasing the specimen temperature from 475° to 600°C. It would appear that direct observation of a chromium-depleted ferrite is impossible by magnetic means. The nonmagnetic residue of sample E was examined for a low-temperature Curie point down to -195°C (-319°F). A slight tractive force was observed at -195°C for this sample which might have been due to paramagnetism just above the Curie point. From the work of Adcock,¹⁵ a Curie point below -195°C indicates a chromium content in excess of 78 pct.

Experimental Results

The experimental results described in the preceding sections indicate the formation of a sub-microscopic precipitate during the embrittlement of ferritic chromium alloy steels at 885°F.

The electron and X-ray diffraction measurements show that the precipitate has the body-centered cubic structure with lattice parameter between that of iron and chromium. This lattice parameter of 2.878Å is equal to that of a pure alloy of 70 pct Cr-30 pct Fe. Chemical analyses of the residues extracted from embrittled steels indicate that the precipitate is between 78 to 82 pct Cr and that the precipitate can amount to as much as 10 pct by weight in a 27 pct Cr steel exposed for four years. X-ray fluorescence analysis of the extract from a high-purity 27 pct Cr iron aged 1000 hr at 900°F showed a chromium content of 92 to 94 pct Cr.

Magnetic measurements on the precipitate show that it is not ferromagnetic above -195°C, which is the Curie point for a 78 pct Cr-22 pct Fe alloy. Electron microscope observations reveal that the diameter of the precipitate particles depends both on time of exposure and on chromium content of the steel. In 27 pct Cr steels the precipitate diameter varied from less than 50Å after 1000 hr exposure to about 225Å after 34,000 hr exposure. For 10,000 hr exposure, diameter varied from about 125Å in a 15 pct Cr steel to about 200Å in a 27 pct Cr steel. The precipitate particles formed during 34,000 hr at 900°F completely dissolved during 1 hr reheating at 1200°F and shrank from 225 to 120Å in diameter during ¼ hr at 1100°F.

The precipitate was found in steels with chromium contents above 14 pct and was found to coexist with σ (FeCr) in steels which had been severely cold-worked before exposure at 885°F. In well annealed 27 pct Cr steels, σ phase was found after exposure at 1050° and 1200°F in samples that increased in hardness during aging and was not found in samples that did not harden at these temperatures. No precipitate was found to form above 1000°F.

Discussion

As stated in the introduction, changes in properties of ferritic chromium steels during embrittle-

ment at 885°F are accompanied by precipitation of a chromium-rich phase. The small particles of the embrittling phase have the body-centered cubic structure of the matrix with a lattice parameter only 0.2 pct larger and are probably coherent with the matrix, thus greatly increasing its hardness due to internal strains. The formation of a fine precipitate also explains the increase in the coercive force of the steel. Chromium depletion of the matrix during embrittlement lowers the corrosion resistance of the steel and also lowers its electrical resistivity. Data in the literature³⁰ suggest that the rate of corrosion for embrittled steels is several times greater than for a steel of chromium content equal to the composition of the depleted matrix (as calculated in this report). This effect could well be due to the presence of the precipitate particles in the steel.

Formation of the precipitate is difficult to explain. The Fe-Cr phase diagram indicates that ferrite and σ phase should be the stable phases in an equilibrated 27 pct Cr alloy; nevertheless during exposure at 885°F the alloy seems to prefer to separate into iron-rich and chromium-rich ferrites. However, in severely cold-worked steels the precipitate can coexist with σ at 885°F. Rate of growth of the precipitate is unusually slow. From diffusion considerations, the precipitate particles could grow to the observed 200Å diameter in less than 2 hr or, alternatively, in 34,000 hr the diffusion-limited diameter is more than 5000Å. In the cold-worked samples aged at 900°F the largest σ particles were within 20 pct of the calculated diffusion-limited size.

The size and structure of the precipitate is reminiscent of the "clusters," "knots," or "complexes"¹⁷ proposed to account for the changes in properties during age-hardening of nonferrous metals that occur before any microstructural changes can be discerned. Various transitional structures preceding formation of the equilibrium precipitate have been observed^{18, 19} by X-ray scattering at small angles from nonferrous metals undergoing age-hardening. In most cases the data have been interpreted as scattering from a two dimensional platelet but occasionally as from a spherical precipitate. The theory of these coherent transitional precipitates, as developed so far,^{19, 20} implies that the thickness of the platelet depends on the mismatch between the atom-atom distances in the precipitate and in the matrix, and also on the relative rigidity of the precipitate and the matrix. According to this theory, the small amount of mismatch between the chromium-rich body-centered cubic precipitate and the matrix, and the greater rigidity of the precipitate, could result in very thick platelets or essentially spheres.

If 885°F embrittlement is an age-hardening phenomenon it should exhibit overaging. This has not been observed for 27 pct Cr steels even after four years of aging. However, it is possible that overaging will be observed after further exposure, since the matrix has been depleted in chromium almost to the threshold composition of embrittlement and little more precipitate can form. The fact that the hardness did not increase during heating from 10,000 to 34,000 hr, while the amount of precipitate more than doubled with no change in particle size, may mean that the particles formed first lost coherency at about the same rate as new coherent particles formed. This idea is supported by the observations that the precipitate size, in a fully embrittled sample held a short time in the softening temperature range, is much larger than in a sample embrittled for just

a short period although the reheated sample is considerably softer. The resolution treatment may cause the precipitate particles to lose coherence while dissolving and thus soften the steel.

Densification and Kinetics of Grain Growth During The Sintering of Chromium Carbide

by H. J. Hamjian and W. G. Lidman

THE fabrication of many materials from powders involves a sintering process. A mass of powder will sinter because of the excess free energy over the same mass in the densified state caused by the higher total surface area of the powder. An understanding of the kinetics and mechanism of sintering should assist in improving the properties of such materials. The present investigation conducted at the NACA Lewis laboratory deals with the sintering of chromium carbide.

Dry sintering (sintering at a temperature below the melting point) was divided into two stages by Shaler:¹ the first stage, during which the particles preserve much of their original shape and the voids are interconnected, and the second stage, during which densification occurs and the pores are isolated. The mechanism of forming interfaces between particles, or welding together of particles, has been investigated by Kuczynski² and may be described by any one or a combination of the following mechanisms: viscous flow, evaporation and condensation, volume diffusion, or surface diffusion. The mechanism by which pores are closed or eliminated (densification) during sintering, is of interest.

Grain growth observed during sintering may be attributed to the variation in the surface energies of individual grains, causing some grains to grow at the expense of others. Grain boundary migration occurs presumably by a diffusion process, therefore the rate of grain growth would be expected to increase exponentially with increasing time and temperature. Thus, for practical sintering times of less than 1 hr, a certain minimum temperature may exist at which major structural and property changes will occur.

Densification and kinetics of grain growth during sintering under pressure of chromium carbide were investigated to provide additional information which will aid in describing more accurately the sintering process and the mechanisms involved. This material was selected for this study because of the current interest in high strength, oxidation resistant refractory materials, such as carbides, which are sintered to produce solid, dense materials from powders. Sintering under pressure is a process where the heat and pressure are applied to the compact simultaneously, specimens for this work were prepared by

sintering under pressure at different temperatures and for various time periods.

Experimental Procedure

Preparation of Specimens: Chemical analysis of the commercial chromium carbide used in this investigation was as follows: Cr 86.19 pct, C 12.14 pct, and Fe 0.2 pct. X-ray diffraction powder patterns gave characteristic diffraction lines of Cr_3C_2 crystal structure.

Powder particle size was determined microscopically and the average initial particle size was 6 microns with 85 pct between 2 and 10 microns. Specimens sintered under pressure were formed in graphite dies³ heated by induction. Sintering temperatures were measured with an optical pyrometer by sighting into a $\frac{3}{8}$ -in. hole drilled 1 in. deep at the midsection of the graphite die. A load of approximately 1 ton per sq in. was applied to the powder. The die assembly was heated in 20 min to the highest temperature (2500°F) at which no increase in grain size could be observed, and less than 2.5 min were required to heat from this temperature to the maximum temperature (3000°F). Sintering temperatures and times for the specimens of this investigation are indicated in Table I.

Analysis of Specimens: Specimens polished with diamond abrasives were etched to reveal the grain boundaries with a 1:1 mixture of 20 pct potassium hydroxide and 20 pct potassium ferricyanide heated to 160°F. Representative areas of each sample were photographed at 1000 diameters. The largest diameters of all well-defined grains were measured, but only the measurements of 15 of the largest grains were averaged in order to determine an index of grain size on the assumption that they were among the first to begin growth.

Densities were determined from differential weighing of the samples in air and water. The reported density values are considered correct within ± 0.01 g per milliliter.

Results and Discussion

Metal compacts have exhibited grain growth when sintered at temperatures about two-thirds of the absolute temperature of their melting point.⁴ Grain growth also occurs during the sintering of chromium carbide and is illustrated by the micrographs shown in Fig. 1. These micrographs were prepared from specimens sintered for 90 min at temperatures ranging from 1371°C (2500°F) to 1648°C (3000°F). Average grain size and density measurements of specimens investigated are presented in Table I. The relationship between grain size and sintering tem-

perature of samples shown in Fig. 1 is graphically represented in Fig. 2.

Grain growth in polycrystalline solids and in sintered bodies may occur by grain boundary migration which results in the gradual absorption of some grains by others. When sintering a mass of polycrystalline nonductile particles, grain growth probably occurs first within the particle boundaries. This internal grain growth (that is, within the particles) is assumed of little importance in the sintering process.⁵ Grain boundary migration across the particle boundaries begins after sintering has proceeded to a point at which substantial bonds are formed between particles which permit absorption of one grain by another. This welding or bonding of particles together has been investigated by Kuczynski.² Based on the results of the present investigation the bonding between particles may be classed as a first stage in the sintering process. A second and third stage become apparent when the density and grain size data are plotted as shown in Fig. 3. Sections of representative micrographs which show the size and position of the pores with different grain sizes have been included in this figure. This curve shows the

dependence of density on the change in grain size. The dashed portion of this curve shows that density increases with increasing grain size and may be designated as a second stage of sintering. A third stage is indicated by the solid portion, where grain size continues to increase with no appreciable increase in density. From the micrographs on this figure and those in Fig. 1 it can be seen that for specimens sintered at times and temperatures which fall in the second stage of sintering the pores are located in the grain boundaries. During the second stage, as the time and temperature conditions are increased, the pores decrease in number and size, and spheroidize while the grains grow. When specimens are sintered at conditions encountered in the third stage densification is complete, the pores have spheroidized and tend to be located within the grains and the grains continue to grow. The sintering process for chromium carbide may therefore be described by a first stage during which particles preserve much of their original shape and a substantial bond has formed between adjacent particles; a second stage during which densification occurs (pores reduce in number and size and spheroidize) accom-

Fig. 2—Variation in average grain size of sintered chromium carbide with sintering temperature, time period of 90 min.

panied by grain growth, and a third stage during which there is no appreciable change in density, the few remaining pores tend to be located within the grains and grain growth is the predominant phenomena. In preparing compacts with maximum density and minimum grain size, sintering must be terminated in the early part of this third stage.

In order to determine whether grain growth during the sintering of chromium carbide could be expressed by an empirical equation, the average measured grain size was plotted against sintering time on logarithmic scales for constant sintering temperature (Fig. 4). Straight lines are apparent with two slopes which again demonstrates that there is a change in the sintering process. The relation-

ship between grain size and sintering time is expressed by the empirical equation

$$D^n = Kt \quad [1]$$

where D is the average grain size in microns; K , the rate constant (function of temperature and n); n , the reciprocal of the slope and constant for each sintering stage; and t , the sintering time in minutes.

The dashed lines which represent the data from specimens sintered for 360 min or less at 1371° and 1426°C (2500° and 2600°F) and for less than about 100 min at 1482°C (2700°F) are parallel and the reciprocal of the slope (n) is 10. A change in slope is observed for sintering times in excess of about 100 min at 1482°C (2700°F) and indicates the change in the sintering process. This change occurs in less than 5 min at 1538°C (2800°F) and above; all these solid lines are parallel and yield a value of n equal to 6. Examination of the structure of specimens sintered for conditions when n is 10 shows that the specimens are in the second stage as described earlier, that is, the pores are located in the grain boundaries and are decreasing in number, size and are spheroidizing while grain growth is occurring simultaneously. Micrographs of specimens sintered for conditions when n is 6 show the pores are spheroidized and tend to be located within the grains while the grains continue to grow; these specimens are in the third stage of sintering. There is no appreciable change in density during the third stage since the mechanism of eliminating the pores within

Fig. 3—Variation of density with grain size for specimens sintered at different temperatures and time periods.

Fig. 4—Isothermal grain growth for sintered chromium carbide.

the grains is probably by self-diffusion which is a relatively slow process. The change in structure that is observed for each value of n corroborates the stage transition as shown in Fig. 3 and the value of n can therefore be associated with stages of sintering. The lower value of n (6) indicates that grain growth proceeds more rapidly during the third stage of sintering.

Grain growth during the sintering process appears to obey the Arrhenius type equation

$$K = Ae^{-Q/RT}$$

where K is a rate constant for sintering process (Eq. 1); A , a constant; Q , the molal energy of activation in cal per mol; R , the gas constant (1.99 cal per mol per °K); and T , the absolute temperature, °K. Thus

$$\ln K = n \ln D - \ln t = -\frac{Q}{RT} + \ln A$$

For a fixed grain size (D) and a given value n or stage, the plot of $\ln t$ against $1/T$ should give a straight line of slope Q/R . From Fig. 5 this relation appears to be valid for each stage of sintering (n is constant). Thus, in a certain time t_1 at an absolute temperature T_1 and in a time t_2 at a different absolute temperature T_2 (for a constant n), a given

Fig. 5—Variation of sintering time to obtain average grain size of 8.5 and 15 microns with reciprocal of absolute sintering temperature.

Table II. Values of Energy of Activation

Sintering Stage	Reciprocal of Slope (n)	Grain Size, Micron (D)	Energy of Activation, Q, Cal per Mol
2	10	8.5	172,000
3	6	15.0	140,000

grain size can be obtained. The relation between these four quantities may be expressed as

$$\ln \frac{t_1}{t_2} = \frac{Q}{R} \left(\frac{1}{T_1} - \frac{1}{T_2} \right)$$

The values of Q obtained from Fig. 5 are shown in Table II.

During the second stage of sintering, the process consists of the complex mechanisms of densification as well as grain growth. The higher values of n (10) and activation energy (172,000 cal per mol) suggest that the pores in the grain boundaries during this stage act as barriers to grain growth. When n is 6 for the third stage, the pores are within the grains and no longer retard the grain growth process. In this stage there is no appreciable densification, grain growth proceeds more rapidly, and the resultant lower value of Q may be interpreted as the activation energy for grain growth.

Conclusions

The investigation of the densification and grain growth phenomena during the sintering of chromium carbide under pressure indicated that:

1—Densification (reduction in number, size, and spheroidization of pores) takes place during a second stage of the sintering process and grain growth occurs simultaneously.

2—After densification is nearly complete (when pores are located within the grains) grain growth continues; this may be considered as a third stage in the sintering process.

3—Grain growth during sintering follows the empirical equation $D^n = Kt$, where D is the grain diameter, K is a rate constant, and t is the sintering time. A change in n is associated with the second and third stages of sintering.

4—An activation energy for grain growth during the third stage of sintering chromium carbide can be computed.

Acknowledgments

The authors wish to express their appreciation to the National Advisory Committee for Aeronautics for permission to publish the results of this investigation. They also wish to acknowledge their indebtedness to the other members of Materials Research Section of the Lewis Laboratory for their assistance in various phases of work.

Deformation of Ferrite Single Crystals

by F. L. Vogel, Jr. and R. M. Brick

THE elementary mechanism of deformation in the body-centered cubic metals has been a subject of dispute for many years. If the problem were merely that of designating the crystallographic plane or planes of slip, the solution would have appeared long ago. However, there must be greater differences in the deformation behaviors of the body-centered and face-centered types than the differences in their lattices would suggest. The lines of slip formed on the polished surface of a strained face-centered cubic metal conform to glide over a single plane of the crystal. Slip in body-centered cubic iron, however, is frequently observed as curved and forked lines which could not possibly define a single plane of atoms. This alone is sufficient reason to expect different modes of deformation to operate in the two lattice types.

The literature in this field now has generally accepted the proposition that {110}, {112}, or {123} planes will act as slip planes in iron. It is essential that the experimental evidence supposedly supporting this proposition be critically examined.

Taylor and Elam¹ in 1926, using relatively small single crystals, determined the operative slip systems by measurements of the distortion of a grid engraved on the specimens prior to deformation. Their results indicated that shearing had taken place in the close-packed direction on a plane adjacent to or coinciding with the plane of maximum shear which contained the slip direction. This led the authors to propose a theory of noncrystallographic

or banal slip. The authors considered an alternate rationalization of banal glide. Slip on two {110} planes or possibly two {112} planes containing the same $\langle 111 \rangle$ direction could produce the wavy slip lines. By employing plane segments of varying widths, the integrated plane could take any position in the $\langle 111 \rangle$ zone. They rejected this explanation, however, feeling that the preponderance of evidence was against it.

Taylor² continued the investigation of the plasticity of the body-centered cubic lattice on β brass. He reasoned that the resistance to shearing of a given plane in the zone of the slip direction was a function of the angle between the glide plane and the closest (110):

$$F = \frac{P}{A} \cos \xi \sin \xi \cos(\chi - \psi) \quad [1]$$

where F is the resistance to shear; P , the axial load at yielding; A , the cross sectional area; ξ , the angle between slip direction and load axis; χ , the angle between plane of maximum shear containing the slip direction and the (101) pole; and ψ , the angle between observed glide plane and the $(\bar{1}01)$ pole.

Differentiating Eq. 1 and rearranging,

$$\frac{dF}{F} = \tan(\chi - \psi) d\psi \quad [2]$$

which expresses the variation of the shear resistance with the angle ψ . Integrating this equation between the limits 0 and ψ yields

$$\ln F/F_0 = \int_0^\psi \tan(\chi - \psi) d\psi \quad [3]$$

Here, F_0 is the resistance to shear of the (110) plane and F is the resistance to shear of a plane ψ degrees from the (110). Thus, the variation of shear resistance with ψ can be calculated from an experimentally measured χ vs ψ relationship.

Fahrenhorst and Schmid³ used several methods, none of them involving direct observation, to determine the glide system in ferrite. They determined the variation of critical resolved shear stress with

This paper is based on a dissertation by F. L. Vogel, Jr. submitted in partial fulfillment of requirements for the degree of Doctor of Philosophy to the Faculty of the Graduate School of the University of Pennsylvania.

orientation assuming that glide had occurred: 1—on planes of the type $\{110\}$, 2—on planes of the type $\{112\}$, 3—on planes of the type $\{123\}$, and 4—on the noncrystallographic plane of maximum shear stress. They state that the assumption that slip had occurred on a $\{123\}$ plane in the $\langle 111 \rangle$ direction best fitted the observed behavior. However, the differences in results between the alternative assumptions are slight and almost certainly less than the experimental error involved in obtaining the data. Equivalent results were obtained from analyses of axis migration or of shear stress-strain data and, although again the interpretation was in terms of $\{123\}$ slip, it appears certain that their tests were incapable of discriminating between the alternative assumptions.

In Barrett, Ansel, and Mehl's extensive study of slip in iron and silicon ferrite,⁶ no critical shear stress values were measured and the investigation was confined to a qualitative evaluation of the glide process. Deformation was induced in thin strip specimens over a wide range of temperatures extending from 500°C down to -195°C. Because of the specimen shapes, the authors were able to plot the traces of the glide markings in only one dimension, i.e., represented by lines on a stereographic projection. Planes of the types $\{110\}$, $\{112\}$, and $\{123\}$ were considered by this method and it was found that all of the 194 traces tabulated could be attributed to one of these three planes. The assumptions of this approach, however, exclude the possibility of determining a noncrystallographic plane of glide and should glide have occurred this way, an adjacent crystal plane would have been recorded as responsible for the marking. When as many different planes as this are under consideration, a trace normal placed at random in the projection has a relatively high probability of coming close to a crystal pole within the limits of error of the measurements. Therefore this investigation did not prove uniquely that slip in iron occurs on the crystal planes $\{110\}$, $\{112\}$, and $\{123\}$.

Andrade⁵ has concluded that in the body-centered cubic metals, all three of the planes $\{110\}$, $\{112\}$, and $\{123\}$ are possible slip planes and the temperature determines which shall operate. This viewpoint, while convenient, ignores significant facts which bear on the case of iron; viz., that at the same temperature, all three of the planes have been reported as planes of slip.

Chen and Maddin⁸ induced strain in molybdenum single crystals at room temperature and found that the glide ellipse could not be accounted for by the indices $\{112\}$ as predicted by Andrade. The glide ellipses which were observed in several specimens took various positions along the $\langle 111 \rangle$ zone. The authors analyzed the asterism which appeared on the Laue photographs of the deformed specimens and concluded that slip had taken place on $\{110\}$ planes regardless of the position of the glide ellipse. This theory had been proposed before by Greninger and by Taylor and Elam. It explains two of the common observations of the slip in iron: 1—that the glide plane may take any position between the $\{110\}$ and $\{112\}$ poles, and 2—that the glide plane will be irregular or wavy when viewed at the head of the ellipse and relatively straight when viewed at the side of the ellipse. The double $\{110\}$ shear hypothesis, however, fails to explain the observed behavior when the plane of glide actually coincides with a $\{110\}$ pole. Here, it would be predicted that in de-

Fig. 1—Single-crystal tensile test specimens. a—Test bar macroetched to reveal single-crystal gage section and polycrystalline shoulders. b—Polished bar for tests at room temperature and above. c—Modification I for tests at -70°C. d—Modification II for tests at -105°C.

tail the glide ellipse should be composed of only one type of plane, a $\{110\}$, and therefore the slip line should be straight, regardless of where it is viewed with respect to the slip direction. This is not borne out by observations.

The analysis by Opinsky and Smoluchowski⁷ of slip in iron is similar to Taylor's in that the position of the glide plane is used to determine the relative resistances to shearing of planes along the zone of the slip direction. A cardinal point of difference between Taylor's approach and that of Opinsky and Smoluchowski is the implicit assumption of the latter that the glide which is observed and measured is on a crystallographic plane, $\{110\}$, $\{112\}$, or $\{123\}$. In a second paper,⁸ Opinsky and Smoluchowski measured the ratios of the critical shear strengths on these planes at various temperatures on compressed silicon ferrite crystals. The results show, as in ref. 4, that at low temperatures there is a preference for $\{110\}$ as the plane of glide in compression.

Experimental Work

Materials and Treatment: Tensile test bars with a $1 \times \frac{1}{4}$ in. diam gage section were machined from $\frac{1}{2}$ -in. rods of ingot iron. Single crystals were grown in the gage section by the strain anneal method described by Stone.⁹ The test bars were first annealed in helium to a ferritic grain size of ASTM 1. Each bar was given a uniform strain in tension of 3.7 pct reduction of area and returned to the helium tube furnace for program annealing. The temperature was rapidly brought to 450°C and then raised to 880°C at an average rate of 60°C per day. The specimens were held at 880°C for several days to absorb some of the small crystallites distributed throughout the single crystals. After furnace cooling, the specimens were etched deeply with 4 pct nital to determine which were single crystals. An average of about 50 pct of these trials resulted in the production of satisfactory single crystals. A large portion of the failures were bicrystals.

Electrolytic polishing of the ingot iron was not feasible because of pitting around oxide inclusions. Therefore, polishing of the single crystals was begun by abrading carefully through No. 600 grit Wet-or-Dry paper. Then, the roughly polished single crys-

Fig. 2—Standard projection of all crystals tested in this investigation.

tals were annealed in helium for four days at 880°C. This anneal gave a fairly good polish and minimized strains which may have resulted from the grinding. Laue photograms taken of all specimens after this polishing treatment had undistorted spots.

The crystals prepared in this manner were found to be satisfactory for the tests at room temperature and above. However, in preliminary tests at -70°C, the bars broke in the grain boundary between the single crystal gage section and the polycrystalline shoulders before yielding occurred in the single crystal. To eliminate this difficulty, the single-crystal bars were very carefully turned to a diameter of 0.200 in. and a length of 3/4 in., Fig. 1c. This modification reduced the load necessary for yielding of the gage section without reducing the load-bearing properties of the boundary and the tests at -70°C were performed successfully. The crystals so modified were helium anneal-polished at 880°C as before and examined by Laue back-reflection for distortion. Crystals which showed asterism or blurring of the spots were rejected.

Preliminary tests at -105°C indicated that the bars which were modified for use at -70°C were unsatisfactory at the lower temperature with brittle failure again occurring in the boundary at the shoulder. The gage length could be machined no more and therefore, a second modification was necessary. Fig. 1a shows that the single crystal extends out of the reduced section into the radius of the shoulder. New ends, 1/4 in. in diameter, were turned on the bars and threaded down to the 0.200 in. gage section. Now, two or more turns of threads extended onto the single crystal above the fillet and a considerable portion of the load was taken off of the boundary zone. This second modification was made without any working or loading the gage section in any way.

Fig. 3—Projection of crystal 104. P_0, P_1 specimen axis before and after deformation. M.S., pole of maximum shear plane containing [111]. G.P., pole of glide plane. S.D., slip direction.

It appeared desirable to ascertain whether the slip behavior of iron was the same in compression as in tension. For that purpose, compression specimens were prepared by scribing a fiducial mark running the length of the gage sections and up onto the shoulders on two test bars. These were then carefully cut into four single-crystal compression cylinders 1/4 in. in diam x 1/4 in. high. The compression faces of each specimen were polished to reduce lateral friction forces during testing.

Apparatus and Procedure: All tests were conducted using a universal testing machine equipped with an autographic load-extension recorder. The extension coordinate of the recorder was actuated by a microformer measuring the movement between the crossheads of the machine. While this device was unsatisfactory for measuring elastic strains in the gage length of the test bars, it was adequate for determining the load at which plastic flow was initiated. A constant reproducible strain rate of 0.01 per min was obtained by use of a strain pacer connected to the recording apparatus.

Provision was made for surrounding the tensile specimens with a suitable heat transfer medium for tests at other than room temperature. A double walled vessel with external insulation was suspended from the stationary crosshead support of the tensile machine. The lower specimen grip passed through the bottom of the vessel by means of a very flexible hose coupling which allowed slight misalignment of the vessel without subjecting the specimen to lateral loading. Axial loading was assured by the use of hardened chains as loading members.

At -105°C, Freon 12 was employed as the heat-transfer medium and was cooled by means of a pyrometrically controlled flow of liquid air through coils immersed in the test vessels. The temperature was maintained constant to $\pm 3^\circ\text{C}$. At -70°C, a mixture of dry ice and acetone was used and for 100°C, distilled water was maintained at its boiling point by an immersion heater. At 190°C, oil was used as the heat transfer medium with a controlled input of current through a Calrod immersion unit supplying the necessary heat.

Prior to testing, the orientation of each single crystal was determined by the Laue back-reflection method. In order uniquely to relate the orientation of the glide plane to the crystal, a line was scribed on the specimen as a fiducial mark of zero degrees azimuth to which rotations around the axis of the specimen could be referred.

For a series of tests at a given temperature, single crystals were selected with orientations distributed so that the maximum shear stress would fall at separated points along the zone of the slip direction. The crystals were extended to an elongation of 6 to 8 pct at the prescribed strain rate, removed, cleaned with alcohol, and dried in compressed air. A Laue photogram using the same convention as before was taken after each extension. In all cases, observations on the glide ellipses were referred to the Lauegram taken after deformation. These in general showed no asterism.

The angles which the traces of the glide or twinning planes made with respect to the crystal axis and the fiducial mark were measured with a goniometer mount on the rotating stage of a Zeiss Neophot microscope. The angle of inclination of a glide trace with the specimen axis was obtained at azimuthal positions of every 10° to 15° rotation of the specimen. Transferred to a stereographic projection,

Fig. 4—Relative position of maximum shear stress poles (dots) and glide plane poles (crosses) along the zone [111].

this series of points plotted as a great circle and the pole of this circle located the position of the glide plane, Fig. 3. Many difficulties were involved in obtaining these measurements with a reasonable degree of accuracy. Preliminary tests showed that at least 4 pct strain was necessary to see any lines micrographically, i.e., at $\times 100$ to $\times 500$ magnification. With small amounts of shear, the lines appeared as a field of faint, blurred striations. When the lines were viewed on a plane perpendicular to the plane containing the slip direction and specimen axis, the waviness became severe and only a general direction was evident. It is estimated that the error in determinations of the glide plane position in this work is in the vicinity of $\pm 4^\circ$.

In the case of the compression tests, the sets of four specimens which had been cut from the same bar were cemented together with the fiducial mark aligned on each specimen and on the shoulders. In this way, each group of four specimens could be handled in the same manner as a tension specimen. Any slight misalignment would not cause errors because the microscopic observations were referred to the Laue photogram taken under the same set of conditions.

Determination of Plane of Glide: Fig. 2 shows the orientations of all crystals tested. Fig. 3 is a projection of crystal No. 104 which is shown here to illustrate the measurements which were made. The plane of maximum resolved shear stress containing the slip direction (M.S.) is the plane in the [111] zone having the minimum area. Its pole is located stereographically by projecting a great circle from the slip direction (S.D.) through the stress axis (P) onto the [111] zone. In the crystal of Fig. 3, the observed glide plane lies close to M.S. and on the same [111] zone. The locations of the glide planes with respect to the crystal planes and the M.S. plane are summarized in Fig. 4 for all cases where the information was obtainable. In Fig. 4, angular distances along the [111] zone are plotted on the abscissa. The location of the maximum shear plane is shown by a dot and the location of the microscopically observed glide plane by a cross. It is immediately evident that the glide plane frequently is not a usual crystallographic plane nor does it conform to the plane of maximum shear stress. However, in most of the tension tests, the glide plane is close to the M.S. plane but inclined away from it toward the $(\bar{1}01)$ plane. This deviation of the glide plane from

the plane of maximum shear is plotted in Fig. 5 as χ , the angle between the $(\bar{1}01)$ to the glide plane. Now, an order to the data becomes apparent. The values of χ vs ψ for a given temperature fall generally on one curve in tension and on another curve in compression, Fig. 6.

Examination of Fig. 4 shows that of the 24 crystals analyzed for slip the observed glide plane is:

- In 6 cases within 5° of (110)
- 3 cases within 5° of (112)
- 7 cases within 5° of (123)
- 9 cases within 5° of none of the above planes
- 10 cases within 5° of maximum shear stress plane in $\langle 111 \rangle$ zone.

Therefore it is concluded that slip in ferrite crystals does not necessarily occur either on a simple crystallographic plane or on the plane of maximum shear stress.

The selection of the glide plane in body-centered cubic ferrite apparently is more complicated than in the case of the close-packed lattices. Analyses of the plots of χ vs ψ of Figs. 5 and 6 using a graphical integration of Eq. 3 show the relative strengths of planes in the $\langle 111 \rangle$ zone for ingot iron at 28° and -70°C to be as given in Fig. 7. The reliability of these results depends on the error and scatter of data.

In obtaining the location of the glide ellipse of Fig. 3, for example, the angular data from the microscope were plotted on a blank sheet. After determining the location of the pole of the glide plane, this was superimposed on a projection of the crystal orientation. Taking care to eliminate conscious or unconscious influences on positioning of the glide plane, it was found that the pole of the glide plane was never more than $1\frac{1}{2}^\circ$ away from the $\{110\}$ to $\{112\}$ great circle. Therefore, assuming a maximum error of $\pm 4^\circ$ to 5° along this great circle would seem to be conservative.

Fig. 5—Relation between χ , angle between $(\bar{1}01)$ and maximum shear stress plane, and ψ , angle between $(\bar{1}01)$ and glide plane, for single crystals strained in tension.

Fig. 6—Relation between angles χ and ψ for single crystals strained in compression.

Fig. 7—Ratio of force required for initial shear on any plane in the [111] zone to force required for shear on the (101).

From +100° to -105°C, there is an evident tendency for the χ - ψ curves to lay below each other. Nevertheless, these χ vs ψ plots are not necessarily precisely defined lines and some points are appreciably off, particularly the 190°C data points which appear to be out of place. This may be a result of strain aging of ingot iron which at 190°C would be very rapid and could influence the glide plane selection.

The Taylor analysis is general and may be applied whenever deformation takes place in a specific crystallographic direction. The face-centered cubic metals are a special case where the slip can occur only on the planes of close packing because their resistance to shear is so very much lower than the resistance of adjacent planes.

The law of constant resolved shear stress which has been proven for the close-packed lattices does not hold in precisely the same way for the deformation of the body-centered cubic lattice. In the latter case, since deformation can occur on a variety of planes of differing shearing strengths, the critical shear stress on the glide plane is a function of orientation. However, the critical shear stress on any

Fig. 8—Temperature dependence of critical resolved shear stress for ingot iron single crystals; circles represent tension tests, crosses represent compression tests.

plane can be calculated so that critical stress values can be put on a common basis for comparison. Except for the selection of the plane of glide, this variation of resistance to shearing is of minor importance because it is not great. For the case in tension at 28°C (Fig. 7), the maximum variation is about 9 pct from (101) to (211). Estimating the accuracy of critical stress measurements at 10 pct, this variation would not be detectable by direct methods. For this reason, the F over F_0 vs ψ curves which were obtained from the measurements of χ and ψ cannot be checked against the experimentally determined shear stress values.

The treatment of the results of this investigation differs from Taylor's² on at least one major item. Taylor drew two curves through his χ vs ψ points obtained in tension and compression, but the distinction between the two curves was on the basis of orientation of the specimen axis in the basic stereographic triangle and the direction of shearing. A great circle drawn from the $\langle 111 \rangle$ slip direction to the (101) pole divides the basic triangle into two areas. Taylor found that compression specimens falling in one area and tension specimens in the other had χ vs ψ values on one curve, and the situation was reversed for the other curve. Analysis shows

Fig. 9—Macrograph of surface markings on specimen No. 96 after deformation at room temperature. X3.

that Taylor's specimens could have been equally well distinguished on the sole basis of whether they were deformed in tension or compression.

A qualitative comparison can be made between the F/F_0 values obtained here and the shear stress ratios calculated by Opinsky and Smoluchowski. Their shear stress ratios are not the same in tension and compression at room temperature which agrees with this investigation. They found that in compression, an increase in temperature produces a decrease in the resistance to shearing of the (112) plane with respect to the shearing resistance of the (110) plane. This compares favorably with the relative slopes of the two F/F_0 curves of Fig. 7. While the numerical values should not check exactly because of the differences of the materials, it can be seen that the relative orders of magnitudes of the critical shearing stresses are the same. For instance, $S_{(112)}/S_{(110)} = 1.06$ from Opinsky at 190°C compared with $F/F_0 = 1.03$ from this research. That Opinsky's value is the higher is in agreement with the observation that silicon increases the tendency for glide to occur in the vicinity of the (110) pole.

Temperature Dependence of Resistance to Shear: The critical shear stress values calculated from the observed yield point values and the glide planes and directions are plotted against test temperature in Fig. 8. These critical shear values presumably should not be averaged at a given temperature because as the value of ψ varies, the shear strength of the plane

a—Viewed in plane almost parallel to slip direction. b—Viewed in plane 45° from slip direction. c—Viewed in plane perpendicular to plane of slip direction and specimen axis.

Fig. 10—Slip lines on specimen 3-c (compression). X150. Area reduced approximately 25 pct for reproduction.

may vary. In most cases, however, the change brought about by converting F values to F_0 values (Eq. 3) is less than the observed scatter in critical shear stress values. This is another manifestation of the fact that F over F_0 ratios cannot be determined with sufficient accuracy by stress measurements. The average value of the critical resolved shear stress at room temperature of 6140 psi from Fig. 8 compares well with Fahrenhorst and Schmid's value of 6340 psi for ingot iron.

The Yield Point: A striking correlation was obtained between the appearance of inhomogeneous yielding and macroscopic surface markings on these ingot iron crystal specimens. In tension, double yielding, or a drop in load at the start of plasticity was observed at room temperature and -70°C . As the temperature was increased, inhomogeneous yielding became less apparent and disappeared finally at 190°C , where a smooth transition existed between the elastic and plastic states of strain. Specimens which showed discontinuous yielding also showed large surface markings, akin to the glide ellipses, which could be seen by the naked eye, Fig. 9. None of the compression specimens showed inhomogeneous yielding even when the tensile specimens for the same temperature did. In addition, it was observed that the tensile specimen at -105°C did not show a double yield point despite the fact that it would otherwise be predicted for this low temperature. Further examination revealed a difference between the specimens which yielded inhomogeneously and those which did not. The bars which were used for tensile tests at -70°C and above had polycrystalline shoulders and therefore the load was applied to the single-crystal gage section through polycrystalline material. In the compression specimens, however, and also in the tensile bars for -105°C , the single-crystal sections were loaded directly because of their geometry, Fig. 1d. Apparently, grain boundary material must exist between the single crystal and the area on the ends where the load is applied for inhomogeneous yielding.

The homogeneous yield in the crystal without a grain boundary is in accord with modern theory.¹⁴ The grain boundary, when loaded, can trap and then later discharge to the crystal a sufficient number of dislocations to cause a yield point. The lower dislocation density of the crystal itself is insufficient for inhomogeneous yielding and therefore the presence of a grain boundary is required.

Observations on Luder's Lines and Slip Lines: The yield point phenomenon caused the formation of Luder's lines, as shown in Fig. 9, which after a strain of 1 or 2 pct were readily visible at low magnifications. At $\times 100$ or higher, however, no slip lines

at all were visible. The positions of the Luder's lines were determined at low magnifications and the plane of deformation was always in the $\langle 111 \rangle$ zone. Regular slip lines became observable at $\times 100$ when the crystal was re-strained to a total elongation of 4 pct or more. It was found in all cases where the two sets of lines were separately measured, that the slip lines which developed at greater strains were on the same plane, within the error of determination, as the Luder's lines.

The most striking characteristic of the slip lines in iron is the change in their nature as the plane of view is changed, i.e., they are straight when the plane of view is nearly parallel to the slip direction and they are wavy when the plane of view is perpendicular to the slip direction. This has received sufficient attention in previous papers and need not be amplified here. Fig. 10a, b, and c reproduces micrographs of the same set of slip lines taken at different azimuthal positions on a crystal deformed in tension. No change was apparent in the nature of the lines as either the identity of plane of slip or the temperature was varied. Even in the cases where the glide plane coincided with a crystal plane, e.g., the $(\bar{1}01)$, waviness in the slip direction was present to approximately the same degree.

There was no readily observable difference in the appearance of slip lines developed at different temperatures. The micrographs of Fig. 10 represent a specimen strained 6 pct in compression at -70°C . Specimens compressed or stretched an equivalent amount anywhere in the range -105° to $+190^\circ\text{C}$ showed slip lines whose spacing and degree of straightness were comparable to those of Fig. 10.

An anomalous effect was noticed in the deformation of several crystals. After extension, the colinear lines scribed on each of the shoulders of the test bars showed a relative rotation around the axis of the bar. In crystal No. 133, the top of the bar was rotated 8° with respect to the bottom in the clockwise sense as the bar was viewed from the top. It should be mentioned here that the chains loading the specimen were carefully aligned before testing and could not apply a torsional stress but would permit a torsional strain if the crystal chose to deform in this way.

Twinning: Table I gives an accounting of the occurrence of twinning. This means of deformation was observed in specimens deformed at -105° and -180°C . The twins were readily recognized and distinguished from slip lines by their width, regularity, and brightness or visibility. Table I shows that a $\{112\}$ type of plane was consistently the plane of twinning. Measurements of the inclination of the

Fig. 11—Twins in specimen 3-D deformed at -180°C . Notice twin starting at lower left corner reduces in thickness to a thin line in the center of micrograph. X300.

twin planes were considerably easier to make than measurements of the glide ellipses and therefore the relative accuracy was improved.

It was observed frequently that, as a long twin was followed around a specimen, the width sometimes diminished gradually to a thin wavy line and then disappeared. There is a striking resemblance of the thin wavy line on a disappearing twin to the wavy slip lines although the connection is not obvious. This behavior can be observed in one of the twins in Fig. 11.

There were other manifestations of twinning besides the microscopic. Load-elongation curves of crystals deformed at low temperatures where twinning occurred show an irregularity in the elastic region. Concurrent with each of these instantaneous decreases of load shown in the curves there was a distinct "clicking" sound. Confirmation of the connection between the clicking sound, the drops in load, and the microscopic occurrence of twinning is afforded by specimen No. 113 which, while it was deformed at -105°C , showed none of these evidences of twinning.

Comparison of the three crystals loaded at -105°C provides information on the proposal that there exists a critical resolved stress for twinning. Crystals No. 116 and No. 124 twinned at widely different stresses. In addition, an eligible plane in crystal No. 113 was stressed beyond the value where the other two specimens twinned but no twin bands were to be found. If the critical shear stress on the (112) plane were the criterion for twinning, the critical stresses in No. 116 and No. 124 would have been the same

Table I. Occurrence of Twinning

Specimen Number		Temperature, $^{\circ}\text{C}$	Twin Plane	Resolved Stress on Twin Plane*
113	(Tension)	-105	No Twinning	16,400
116	(Tension)	-105	(112)	4,140
124	(Tension)	-105	(112)	12,700
3-D	(Compression)	-180	(211)	21,000
92-D	(Compression)	-180	(112) (121) (211)	—

* Resolved stress on twinning planes calculated assuming shear in a [111] type direction. In case of No. 116, where there were alternate choices of load values for plane, it was assumed that the most highly stressed plane sheared first. Resolved stresses could not be calculated for 92-D because of the multiplicity of operative planes. The resolved stress listed for No. 113 is the value for the most highly stressed (112) type plane at the yield point.

and No. 113 would have shown evidence of twinning, so it must be concluded that this is not the criterion.

Conclusions

From experiments on the deformation of ingot iron single crystals it may be concluded that:

1—Plastic deformation occurs by apparent glide in the $\langle 111 \rangle$ direction on a plane, not necessarily crystallographically significant, whose identity is determined by two factors:

- The orientation of the crystal with respect to the stress axis
- The variation of the resistance to shear of the planes containing the $\langle 111 \rangle$ glide direction. The interrelation of these two factors is a function of temperature and direction of stress application although the data here for ingot iron are not sufficient to delineate these factors with certainty.

2—The critical stress necessary to produce shear on the glide plane increases sharply below room temperature. From room temperature to 200°C the change is slight.

3—The junction of the single crystal and polycrystalline shoulders of these ingot iron specimens is a grain boundary region of pronounced brittleness at low temperatures.

4—Inhomogeneous yielding may occur at room temperature and below when an ingot iron single crystal is stressed through the grain boundary junction. Luder's lines appear in the single crystal concurrently with the inhomogeneous yield.

5—For static tensile strain rates, twin bands appear on planes of the type (112) for specimens deformed at -105°C or below. The criterion for twinning on the (112) plane is not a critical resolved shear stress.

Vapor Pressure of Silver

by C. Law McCabe and C. Ernest Birchenall

IN attempting to extend vapor pressure measurements of the type previously reported by Schadel and Birchenall¹ for silver and by Schadel, Derge, and Birchenall² for silver-silicon to other systems, it was observed that the materials melted at indicated temperatures 10° to 15° below their accepted melting points. Further investigation revealed that the thermocouple readings were in error due to appreciable conduction losses along the reference thermocouple wires. If the wire diameter of the reference couple inserted into the Knudsen cell was reduced, the correction for the indicating couple changed in a manner tending to explain the melting behavior. When extrapolated to zero wire diameter from measurements with several reference thermocouples of different wire thickness, the melting point of silver then agreed with the indicated temperature at which silver chips were observed to coalesce into a sphere. Approximately the same calibration was given by observing the melting of small wires of silver or gold in the Knudsen cell connected in series with an ammeter, where the leads into the cell were very fine in order to minimize heat conduction.

Unfortunately neither of these methods seemed to yield a sufficiently precise temperature calibration to match the apparent precision of the other aspects of the vapor pressure measurement. It was decided, therefore, to redetermine the vapor pressure of silver in another setup under conditions permitting precise temperature measurement. The vapor pressure of pure silver could then be used as an internal calibration of temperature in the older unit in making runs on alloys. This has been done; the present report is a correction to ref. 1.

Experimental Procedure

The apparatus, shown in Fig. 1, was very similar to that employed by Harteck,³ except that the orifice sizes were smaller and the residual pressure in the vacuum system was probably much lower. A small, sharp-edged hole, nearly circular in shape, was ground into the rounded end of a quartz tube. The orifice area was then measured by tracing the image at known magnification on graph paper and counting the squares enclosed. The silver specimen was sealed into the tube to make a Knudsen cell. A tantalum jacket surrounding the cell served to increase the uniformity of temperature. This assembly was placed in the bottom of a long quartz tube with an

BIRCHENALL, Junior Member AIME, formerly Member of the Staff, Metals Research Laboratory, Carnegie Institute of Technology, is now Associate Professor of Chemistry, The James Forrestal Research Center, Princeton University, Princeton, N. J.

Discussion on this paper, TP 3512E, may be sent, 2 copies, to AIME by Dec. 1, 1953. Manuscript, Sept. 17, 1952; revision, Dec. 18, 1952. Cleveland Meeting, October 1953.

inside diameter of about 1 in., which was connected to the vacuum system through a ground joint sealed with picein wax well removed from the furnace. A thermocouple tube inserted through the top of the vacuum line reached into the tantalum jacket so that the thermocouple junction was immediately adjacent to the Knudsen cell except for the protection tube wall. A resistance furnace could be raised to cover the end of the quartz tube containing the cell in such a way that the cell was in the uniform temperature zone 13 in. from the end of the furnace. An ionization gage was included in the vacuum system in the cold lines of wide diameter, immediately beyond the ground joint. The vacuum system consisted of a mercury one-stage diffusion pump, backed by a Welch duo-seal mechanical pump. The pumps were separated from the reactor chamber by a dry ice trap. The ionization gage always read less than 10^{-6} mm Hg after initial outgassing and before each run was started.

Each newly filled Knudsen cell was evacuated at high temperature overnight before the first weighing was made. The cell was returned to the system, heated for a measured time at constant temperature, cooled, and reweighed. The heating and cooling times were quite short since the hot furnace was raised to receive the reactor at the beginning of the run and removed again at the end. The tube heated or cooled quickly. The total mass loss was attributed entirely to effusion of silver vapor from the quartz cell, since empty quartz cells maintained constant mass through similar heating cycles. The vaporized silver condensed on the cold walls of the quartz tube extending above the furnace.

Earlier studies in the induction heated unit had shown that the same vapor pressure was found for silver, whether the silver was in contact with the tantalum metal cell or with porcelain or quartz liners.

The Pt-Pt-10 pct Rh thermocouple was calibrated against a secondary standard of the same material and found to agree with the published tables. Always operating in air at temperatures below 1000°C,

Fig. 2—Vapor pressure of silver vs $1/T$.

there was no evidence of couple deterioration. The calibration after the runs checked the initial calibration.

The silver metal was obtained from the U. S. Mint as proof silver, 99.99+ pct Ag. No further analyses were made.

Data and Calculations

Table I gives the pertinent experimental data—the orifice area, a , the temperature, T , the time, t , and the weight loss, G . From these data the pressure, p , may be calculated by the equation for effusion through an orifice

$$p = \frac{G\sqrt{2\pi RT}}{at\sqrt{M}}$$

where R is the gas constant and M is the molecular weight of the effusing vapor. Care was taken in these measurements to keep the orifice diameter

Table I. Vapor Pressure of Silver

Orifice, Area, Sq Cm	Temperature, °K	Time, Min	Wt Loss, Gram Ag	Pressure, Mm Hg
Solid Silver				
0.011725	1133	6020	0.0177	2.32×10^{-4}
0.011725	1143	4825	0.0186	3.06×10^{-4}
0.00643	1171	4390	0.0183	6.10×10^{-4}
0.00643	1183	6832	0.0382	8.22×10^{-4}
0.00643	1204	6850	0.0600	1.30×10^{-3}
0.00643	1213	4385	0.0477	1.62×10^{-3}
0.00643	1223	2540	0.0337	1.98×10^{-3}
0.00170	1224	8510	0.0304	2.05×10^{-3}
Liquid Silver				
0.00170	1235	5835	0.0268	2.60×10^{-3}
0.00170	1245	3980	0.0228	3.27×10^{-3}
0.00170	1253	4175	0.0278	3.83×10^{-3}
0.00170	1263.5	4090	0.0347	4.89×10^{-3}
0.00170	1273	2980	0.0310	6.01×10^{-3}

very small compared with the mean free path of the silver atoms.

Since the range of temperatures was not as great as in the previous study, it was felt that the vapor pressure curves might be established best in the following way. The liquid points reported here and those of von Wartenberg⁴ and Fisher⁵ were plotted as $\log p$ against the reciprocal of the absolute temperature, Fig. 2. The most satisfactory straight line was drawn through these points; there is no apparent systematic deviation. Using the Clapeyron-

Fig. 3—Vapor pressure of silver vs $1/T$. See text for manner in which line was drawn.

Clausius equation, the heat of vaporization was calculated to be 62.60 kcal per gram atom. To find the slope of the vapor pressure line for solid silver, the latent heat of fusion, 2.86 kcal per gram atom given by Kelley,⁶ was added to the heat of vaporization. The heat of sublimation is then 65.46 kcal per gram atom. This value and the vapor pressure at the melting point, 2.51×10^{-3} mm of Hg, taken from the liquid curve, uniquely determine the vapor pressure line for the solid. This line was drawn in Fig. 3, and the experimental points were plotted on it for comparison. The agreement is seen to be excellent. The precision of these measurements seems to be somewhat better than that in the previous study.¹

The vapor pressure equations are for liquid silver

$$\log p = -\frac{62,600}{2.303 RT} + 8.496$$

and for solid silver

$$\log p = -\frac{65,460}{2.303 RT} + 9.003$$

where p is in mm of Hg and R is 1.986 cal per mol per degree.

When ΔH_v° , the heat of vaporization at absolute

zero, is calculated for the points in this study, a value of 67.87 ± 0.10 kcal per gram atom is obtained. The von Wartenberg and Fisher points only give 68.07 ± 0.44 , in good agreement. The average for all points is 68.02 ± 0.29 compared with a previously reported value of 67.71 ± 0.57 . Since the vapor pressures are about 40 pct lower than the earlier ones,¹ while ΔH° has changed little in value and apparent precision, it must be concluded that this is not a particularly sensitive test for vapor pressure data.

Harteck's³ points are still about 30 pct below the present data. However, this discrepancy is of the order to be expected from using too large an orifice and failure to obtain a good enough vacuum. The possibility of some other source exists, however, for a comparison of Harteck's values for gold in the same series of measurements with the recent work of Hall⁷ finds Harteck too low by a factor of almost 6. Since gold had a much lower vapor pressure than silver in Harteck's measurements, the mean free path condition was probably not violated by too

large an orifice. The only obvious source of this discrepancy lies in a very poor vacuum.
